SUBJECT INDEX

A

- ABSCESS, subdural: a clinicopathologic study [Kubik & Adams] 36—mr
- ADENOCARCINOMA of colon, with jejunocolic fistula [Schatzki & others] 885—cr
- Admiral of the Ocean Sea* (See Sinister Shepherd) 31—c
- ADRENALIN in base suspended in aqueous solution of sodium thioglycolate in treatment of asthma [Naterman] *736
- AGED (See Eczema and pruritus in aged) [Anderson] *653
- AGED DISEASES 853—misc
(See Skin)
- ALBUMINURIA and associated renal changes [Dock] 201—mr
in diagnostic value of serial measurements of ambulatory patients [Derow] *827
- ALCOHOL and cerebral vasodilatation [Loman & Myerson] *439
- ALLERGIC states in selectees, diagnosis of [Hyde] *241
- AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY, Feb. 13, 690—n
- AMERICAN BOARD OF OPHTHALMOLOGY 361—n
- AMERICAN MEDICAL ASSOCIATION, annual meeting of, 81—c
(1943 meeting canceled) 527—MMS
- AMPULLA of Vater, papillary adenocarcinoma of [Adams & others] 265—cr
- ANEMIA, hypochromic, with koilonychia (spoon nails) [Clarke] *338
myeloid metaplasia of spleen with acute hemolytic [Brewster & Wollenman] *822
- ANESTHESIA, regional [Brown & Nicholson] *636
- ANEURYSM [Harwood] 681—cr
dissecting, of aorta, with rupture into mediastinum and left pleural cavity [Richardson & others] 712—cr
intracranial, of internal carotid artery [Botsford] *657
- ANKLE, tuberculosis of, in adults and children [Wasser sug] *436
- ANNOUNCEMENT, Viets, Henry R. 652—n
- AORTA aneurysm [Dieuaide & others] 603—cr
aneurysm [Harwood] 681—cr
coarctation of [Walker] 120—c
dissecting aneurysm of, with rupture into mediastinum and left pleural cavity [Richardson & others] 712—cr
stenosis [White & others] 927—cr
- APPENDICITIS, acute gangrenous, with rupture into root of mesentery [Brailey & others] 645—cr
healing [Franseen & others] 715—cr
- APPENDIX, primary carcinoma of, associated with acute appendicitis [Young & Wyman] *703
- ARGYLL ROBERTSON pupil 491—mc
- ARMY camps, communicable diseases in [Stokes] 237—mr
physician prepares to enter [Zollinger & Freedman] *370
- ARMY-NAVY "E" AWARD to Winthrop Chemical Company 1058—misc
- ARTHRITIS (See Knee contractures) [Kuhns] *975
rheumatoid, associated with splenomegaly and leukopenia [Talkov & others] *395
rheumatoid, treatment of [Short & Bauer] *442
- ASCORBIC acid deficiency associated with gastric lesions [Lund] *247
- ASTHMA, bronchial, use of ether in oil intramuscularly in treatment of [Maietta] *985
therapy [Naterman] *736; [Maietta] *985

- ATELECTASIS, congenital alveolar [Williams & others] 516—cr
- ATHEROSCLEROSIS [Leary] 573—mr
- AUDOMETRY in general practice [Mueller] *617

B

- BACTEREMIA, hemolytic streptococcus [Rantz & Kirby] *730
- BACTERIOLOGICAL Laboratory of Health Department City of Boston 652—n
- BACTERIOLOGY of wounds of compound fractures of skull [Munro] *939
- BALLARD, JAMES F. (See Semicentennial) 610—c
- BASCH, WILLIAM E. R. (See Deprivation of license) 726—c
- BASE HOSPITALS 768
- BASILAR artery, thrombosis of [Kubik & others] 844—cr
- BILE pigments [Watson] 665, *705
- BILIARY-TRACT diagnosis *470
disease, significance of carotid-sinus reflex in [Engel & Engel] *470
surgery (See Rubber tube in biliary tract, retention of) *545
- BIOPSIES, renal, from hypertensive patients [Castleman] 37—mr
- BIRTH CONTROL (See Approaching referendum) 652—c
- BLOOD tests, approved laboratories for premarital [Jakmauh] 571—c
vessel aneurysm [Dieuaide & others] 603—cr
- BLUE SHIELD 197, 806—c
[Greene] 892—c
- BONE cyst, left humerus [Daland & others] 194—cr
device for internal fixation of [Smith] *510
diseases [Mallory] *955
granuloma [Green & others] 840—cr
- BOOK REVIEWS
(Maude) *Abbott: A memoir* [MacDermot] 498
Admiral of the Ocean Sea (See "Sinister Shepherd") [Morison] 31—c

INDEX

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

1942

The date of publication of any case may be determined from the case number. The first two figures of each case number indicate the volume number, 28. The third and fourth figures give the number of the week, dating from January 1. The last figure gives the case number for the week. For example, Case 28421 is the first case for the 42nd week of Volume 28.

- Abscess, of kidney, 28371
 - of liver, 28432
 - of lung, 28271, 28322, 28512
 - retroperitoneal, 28491
 - subdural, 28302
- Adenoma, of parathyroid, 28272, 28311
 - of pituitary, chromophobic type, 28292
- Adrenal, carcinoma of, metastatic, 28271, 28302
 - infarction of, 28292
- Aneurysm, congenital, cerebral, 28151, 28152
 - dissecting, of aorta, with rupture, 28072, 28111, 28202, 28421, 28442, 28451
 - syphilitic, of aorta, 28271
 - with rupture, 28092
- Anomaly, congenital, adhesive band obstructing small bowel, 28062
 - (See also Heart)
- Aorta, hypoplasia of, 28532
 - media necrosis cystica of, 28072, 28442
 - (See also Aneurysm)
- Appendicitis, acute gangrenous, with rupture, 28432
 - healing, 28452
- Appendix, mucocele of, 28051
- Arterioles, hypertrophy of, pulmonary, 28041, 28401
 - with endarteritis, 28041
- Artery, see Aneurysm, Embolism, Heart, Thrombosis
- Bile duct, carcinoma of, 28331
 - stone in, 28121
- Bone, carcinoma of, metastatic, of rib and vertebra, 28191
 - cyst of, humerus, 28312
 - giant cell tumor of, humerus, 28141
 - granuloma of (Hand-Schüller-Christian type), 28101, 28481
 - osteitis fibrosa cystica of, 28311
 - osteoid osteoma of, vertebra, 28291
 - osteomyelitis of, frontal, 28301
 - osteosarcoma of, maxilla, 28142
- Brain, aneurysm, congenital, 28151, 28152
 - carcinoma of, metastatic, 28302
 - embolism of, 28032
 - empyema of, subdural, 28301
 - hemorrhage into, 28151
 - infarct of, 28032, 28482
 - syphilis of, meningovascular, 28332
 - thrombophlebitis, 28301
 - tuberculoma of, 28261
 - tuberculosis of, 28192, 28261
 - (See also Meningitis, Thrombosis)
- Bronchus, cyst of, 28412
 - tuberculosis of, 28201
- Bursitis, tuberculous, 28462
- Carcinoma, of ampulla of Vater, 28331
 - of colon, 28162, 28492
 - of duodenum, 28232
 - of esophagus, 28021, 28322
 - of jejunum, 28181
 - of kidney, 28191, 28342, 28371
 - of liver (hepatoma), 28522
 - of lung, bronchiogenic, 28271, 28282, 28322, 28512
 - of pancreas, 28022, 28031, 28232, 28241, 28471
 - of retroperitoneal nodes, metastatic, from carcinoma of cervix, 28082, 28471
 - of sigmoid, 28172
 - with perforation, 28381
 - of uterus, 28071
- Cholangitis, acute, intrahepatic, 28332
- Choledocholithiasis, intrahepatic, 28121
- Cirrhosis, see Liver
- Colitis, see Intestine
- Cyst of bone, humerus, 28312
 - of kidney, 28342
 - of ovary, 28531
 - bronchiogenic, arising from trachea, 28412
 - echinococcal, 28132, 28461
 - pleuropericardial, 28422
- Degeneration of spinal cord, 28091, 28382
- Diabetes mellitus, 28372
- Diverticulum, see Intestine
- Embolism, of brain, 28032
 - pulmonary, 28022, 28091, 28182
- Emphysema, pulmonary, 28101, 28211
- Empyema, pleural, 28322
 - subdural, 28301
- Endarteritis, pulmonary, 28041
- Endocarditis, see Heart
- Endometriosis, of sigmoid, 28351
 - of uterus, 28351
- Enteritis, see Intestine
- Esophagus, carcinoma of, 28021, 28322
- Fibroma, neuro-, of mediastinum, 28311, 28411
- Fistula, esophagotracheal, 28021
 - ileosigmoidal, 28491
 - jejunal, 28492
- Gall bladder, erosion of, 28332
 - hydrops of, 28241, 28321
- Gangrene of Meckel's diverticulum, 28062
- Hand-Schüller-Christian syndrome, 28101, 28481
- Heart
 - Congenital, interventricular septal defect (cor triloculare) 28532
 - Cor pulmonale, 28041, 28091, 28382, 28401
 - Coronary disease of, thrombosis, 28032, 28182
 - Dilatation of, 28042
 - Endocarditis, bacterial, acute, 28231
 - subacute, mitral, 28341
 - tricuspid (type 6 pneumococcus) 28532
 - calcareous, with stenosis, aortic, 28502
 - rheumatic, chronic, aortic, 28341
 - with stenosis, 28182
 - mitral, with stenosis, 28182, 28341
 - Hypertrophy, hypertensive, 28151
 - idiopathic, 28042, 28102

- Infarction of, 28182
 Pericardium, cyst, pleuropericardial, 28422
 hemo-, 28072, 28111, 28442
 pericarditis, uremic, acute, 28012
Thrombus, mural, right auricle, 28042
 Hemorrhage, pulmonary, 28131
 subarachnoid, 26151
 Hemorrhage, 26092
 Hodgkins disease, see Lymphoma
 Humerus, cyst of, 28312
 giant-cell tumor of, 28141
 Hypernephroma see Kidney, carcinoma of
 Hyperparathyroidism 28272, 26311
 Ileum, see Intestine
 Infarct, of adrenal, 26292
 of brain, 28032, 28492
 of heart, 28192
 of intestine, 28092, 28362
 of kidney, 28231
 of lung, 28042, 28091, 28182
 of omentum, 28061
 of spinal cord, 28092
 Intestine, carcinoma of, 28162, 28172, 26181, 26232, 28497
 with perforation, 28381
 colitis, ulcerative, acute idiopathic with perforation
 28252
 diverticulitis of, 28171
 diverticulum of, Meckel's, 28081
 gangrene of, 28062
 inflammation of, 28452
 endometriosis of, 28351
 fistula of, 28491, 26492
 ileitis, regional, 28081
 infarction of, acute, 28092
 venous, 28362
 intussusception of, 26392
 lymphoma of, clasmotocytic type, 28491
 lymphoblastic type, 26361
 stem cell type, 28242
 obstruction of, 28062
 due to phytobezoar, 28212
 perforation of, (foreign body), 28222
 polyp of, 28392
 tuberculosis of, 28192
 ulcer of, peptic, perforating, 28332
 tuberculous, perforating, 26192
 Kidney, carcinoma of, 28191, 28342
 with abscess, 28371
 cyst of, 28191, 28342
 glomerulosclerosis of, intercapillary, chronic, 28372
 infarct of, 28731
 (See also Nephritis, Nephrolithiasis, Nephrosis)
 Knee, bursitis, tuberculosis of, 28462
 metaplasia, chondromatous, of synovia of, 28127
 Kyphoscoliosis, right dorsal, extreme, 28382
 Liver, abscess of, 26432
 atrophy of, subacute yellow, 28391
 carcinoma of (hepatoma), 28522
 metastatic, 28031, 28471
 cirrhosis of, biliary, 28121
 obstructive, 28101
 portal, 28251
 syphilitic, *hepar lobatum*, 26441
 toxic, 28281, 28522
 cyst of, echinococcal, 28132, 28461
 sarcoïd of, 28161
 Lung, abscess of, 28271, 28322
 atelectasis of, congenital, 28401
 bronchiectasis of, 28021, 28521
 carcinoma of, 28271, 28282, 28322, 28512
 metastatic, 28031, 28191, 28471
 cyst of, arising from trachea, 28412
 edema of, 28511
 embolism of, 28022, 28091, 28182
 emphysema of, 28101, 28211
 fibrosis of, 28211
 hemorrhage into, 28131
 infarct of, 28041, 28091, 28182
 hypertrophy of, arteriolar, 28041, 28401
 with endarteritis, 28041
 pneumonia of, 28211
 thrombosis of, 28022, 28091
 tuberculosis of, bronchus, 28201
 Lymphoma, malignant, clasmotocytic type of mesentery,
 28491
 lymphoblastic type, of ileum, 28361
 Hodgkins sarcoma type, of lymph nodes, spleen and
 bone marrow, 28431
 stem-cell type, of ileum and jejunum, 28242
 Maxilla, osteogenic sarcoma of, 28142
 Medrinum, adenoma of, parathyroid, 28272
 fibroma of, neuro-, 28311, 28411
 Meninges, carcinoma of, metastatic, 28302
 syphilis of, 28332
 tuberculosis of, 28192 28261
 Mucocoele, of appendix, 28051
 Nephritis, glomerulo-, acute, 28131, 28211, 28331, 28262
 chronic, 28012, 28262
 subacute, 28112 28341
 Nephrolithiasis (sulfadiazine), 28271
 Nephrosis, lipoid 28472
 sulfonamide, 28501
 Omentum, cyst of, echinococcal (gastrocolic) 28461
 infarction of, 28061
 Osteitis, fibrosa cystica, 28311
 Osteoma, osteoid, of vertebra, 28291
 Osteomyelitis frontal, 28301
 Ovary, pseudomucinous cyst of, 28531
 Pancreas, carcinoma of, 28022, 28031, 28232, 28241 26471
 fibrosis of (scleritis), 28252
 Pancreatitis, acute, hemorrhagic, 28221, 28511
 chronic, with fat necrosis, 28121 28502
 Parathyroid, adenoma of, 28272, 28311
 hyperplasia of, 28272
 Pericardium, see Heart
 Peritoneum, carcinoma of, metastatic, 28471
 Peritonitis, acute, 26221, 28252, 28332
 bile, 28121
 Cl welchii, 28222
 streptococcal, 28472
 tuberculous, encapsulated, with calcification 28531
 Pituitary, adenoma of, 28792
 Pleura, carcinoma of metastatic 28031
 empyema of, 28322
 Polyp of ileum, 28392
 Pylephlebitis, suppurative, 28432
 Rectum, see Intestine
 Rib, carcinoma of, metastatic, 28191
 Sarcoïd, of liver, 28161
 Sarcoma, Hodgkins, see Lymphoma
 lipo-, of thigh, 28052
 lympho-, see Lymphoma
 osteogenic, of maxilla, 28142
 Sigmoid, see Intestine
 Sinus, thrombophlebitis of, longitudinal, 28301
 Sinusitis frontal, 28301
 Spinal cord, degeneration of 28091, 28382
 infarction of, 28092
 Spleen, lymphoma of, 28431
 Splenomegaly, 28251 28281

Stomach, carcinoma of, 28302
 metastatic, 28471
 Sulfonamide therapy, 28271, 28501
 Synovia, chondromatous metaplasia of, 28122
 Synovioma, of thigh, 28352
 Syphilis, of aorta, with aneurysm, 28271
 rupture of, 28092
 of liver, 28441
 meningovascular, 28332
 Thigh, sarcoma of, lipo-, 28052
 synovioma of, 28352
 Thrombophlebitis, of superior longitudinal sinus, 28301
 Thrombosis, of basilar artery, 28482
 of mesenteric vein, 28082, 28362
 of portal vein, 28082, 28362
 of pulmonary artery, 28022, 28091
 of renal vein, 28471
 of splenic vein, 28082, 28222, 28362, 28471
 (See also Heart, coronary disease of)
 Trachea, cyst of, bronchiogenic, 28412
 Tuberculoma, of brain, 28261
 Tuberculosis, of bronchus, 28201
 of duodenum, with perforation, 28192
 of knee, 28462
 of meninges, 28192, 28261
 of peritoneum, 28011, 28531
 miliary, 28011, 28192
 Ulcer, of duodenum, chronic, with perforation, 28332
 Urolithiasis medicamentosa (sulfadiazine), 28271
 Uterus, endometriosis of, 28351
 carcinoma of, 28071, 28082
 Vein, pylephlebitis of, 28432
 thrombosis of, 28082, 28222, 28362, 28471
 Vena cava, obstruction of, by hepatoma, 28522
 Vertebra, carcinoma of, metastatic, 28191, 28322
 osteoma of, osteoid, 28291

NUMBER 1

THE RELATION OF MEDICINE TO THE EMERGENCY*

FRANK H. LAHEY, M.D.†

BOSTON

CERTAINLY, after what we have been through in this country and what we have seen other countries go through, no one can fail to say that we have been slow to convince, slow to profit by such tragic examples in other countries, slow to suspect and slow to prepare, and that we have likewise been woefully slow in accelerating our war effort. No one can truly say that many of our leaders have not been aware of the foggy nature concerning this situation, or that these leaders have not warned us of our dangers. As a moral example to ourselves as we face our truly dangerous future, we must admit that we have stupidly believed what we wanted to believe, in the face of the fact that to anyone with simple, unbiased sense it was evident that the true situation was what we did not like it to be. Experience is often bitter medicine to take, but even though we seem stupid to ourselves as we review the past year, we should have much to be thankful for if we were even now to learn the lesson that the situation the country finds itself in is not what we should like it to be, and that to make it so will require our every resource in energy, unity, courage, speed and tenacity.

One of the things that has impressed me as I have traveled the country urging on the medical profession the need for physicians is that the country is so sensitized to rumors. If we could only realize that rumors, innuendoes and gossip are such bad things! Whoever heard of a good rumor? A rumor is always bad. If we could but realize that rumors, innuendoes and gossip tend to lend aid to our enemies by promoting confusion, discord and strife, we should, I am sure, avoid the spread of such rumors. I have endeavored to develop for myself a philosophy for this emergency, and it is that in place of rumors I shall employ, when I am so inclined, frank criticism. It has at least the virtue of honesty of purpose, and of willingness to accept the penalties that go with

responsibility if I am wrong. Criticisms of our neighbors and their war efforts — and in times such as these they become prevalent — are often an apology for our own shortcomings or an attempt to publicize and make prominent whatever we have done by attracting attention to it by comparison with others. Conscientious labor and true patriotism are practiced for the convictions that go with them. Their consistent performance brings to the possessors of these convictions all the reward they require. Publicizing of the virtue of patriotism questions not only the pureness of its quality but also, as publicized charity does, the sincerity of its purpose.

Every doctor, I am certain, is particularly interested in what the immediate needs for the services are, and since I am in regular contact with the offices of the Surgeons General in Washington through the Procurement and Assignment Service, it is possible for me to state quite accurately what these needs are. To meet the requirements of its rapidly mounting numbers, the Army must have twelve thousand additional doctors by January 1. To meet the immediate needs of aviation and the Army, it must have seven thousand doctors by July 1. These are not probable needs; they are real needs if we are to maintain the table levels that are now accepted for the Army — 6.5 physicians per 1000 men, 15 dentists, and 0.75 veterinarians.

The immediate need for doctors to go with troops is in the age group up to thirty seven, and for specialists in that up to forty five. Why is it necessary for the Army to have age groups such as these? The reason should be obvious to everyone: this is a war of many and distant fronts. We are all conscious of the fact that cargo space is at a premium, and to ship a doctor of greater age than this is to accept the possibility of his breakdown in a distant place; such an event would require not only more cargo space to get someone there to take his place but also the services of those who have already been transported there to take care of

*An address delivered at the annual banquet of the Massachusetts Medical Society, Boston, May 26, 1942.
†President, American Medical Association.

him; and feed him. This is a bald and plain statement why age groups such as these are desirable.

Older men have frequently asked me whether there would be an opportunity for them in this war. There will undoubtedly be an opportunity for everyone if the war goes on long enough, as it very well may. The demand for doctors will be so great that everyone from all the various age groups will be required either in industry and hospitals, to care for the civilian population, or in other branches of the national endeavor. We must all realize in civilian life that there will be not only adjustments, such as those to sugar and to tires and gasoline rationing, but also, as the situation becomes more acute and the endeavor more prolonged, changes and modifications in medical care; the civilian population must adjust its mind as satisfactorily to these rationings as to the more tangible and obvious ones, such as things to eat, to wear or to ride in.

Finally, I should like to urge the profession in general, particularly physicians under forty-five, who fall under selective-service regulations, to volunteer at once and not wait further. The need for medical personnel, particularly for aviation and the Army, is so urgent that if they are not already

listed by their state chairman of the Procurement and Assignment Service as essential for a medical school, hospital, civilian population or industry, they should by all means immediately seek a commission. Every doctor of forty-five or under must realize that he is actually in the hands of the Selective Service System and that he is being deferred in Class 2-A only up to the time when it is determined that he is either essential—this decision being made by the state committee of the Procurement and Assignment Service—or not essential. Whenever he has been listed as not essential, he becomes literally and actually subject to induction.

It is with no purpose of threat that I make these statements. The Army must have medical personnel. It has deferred by presidential request to the Procurement and Assignment Service until such time as essentialness has been settled, and should it not obtain the necessary number of doctors by voluntary enlistment, there is no way to obtain them except by requesting selective-service boards to change the status of these men from deferred classification in Class 2-A to draftability in Class 1-A. It is to be hoped that compulsion in this emergency will not be necessary.

605 Commonwealth Avenue

THE PROCUREMENT AND ASSIGNMENT SERVICE FOR PHYSICIANS IN MASSACHUSETTS*

REGINALD FITZ, M.D.†

BOSTON

THE Procurement and Assignment Service for Physicians, Dentists and Veterinarians, established recently in the office of Defense, Health and Welfare Services, is an interesting experiment in medical democracy. So far as doctors are concerned, it is designed to give every qualified physician an opportunity to enroll himself in one of the several services demanded by the national need. An enrollment form and a questionnaire have been circulated recently, which all physicians should fill out carefully and at once. Only with the information that will be obtained from these forms can the Procurement and Assignment Service perform its functions intelligently and expeditiously.

The Procurement and Assignment Service for Physicians began to function in Massachusetts on

January 30, 1942. The method by which this service might operate most effectively has necessitated the establishment of a central corps-area committee for New England under the chairmanship of Dr. Walter G. Phippen; under him are appropriate state and district subcommittees whose duties are to obtain as many doctors as possible for military use and at the same time to see to it that the civilian needs of medical care in each community are unhampered. This report of the first three months' experience is now presented by the Massachusetts committee.

The Army, Navy and Public Health Service wish to attract officers as volunteers, not by induction; thus, each person who applies for a commission through the Procurement and Assignment Service does so voluntarily. To be eligible for a commission in any of the national services, a man must be a citizen of the United States and a graduate from a medical school acceptable to the medical departments of the United States Army or Navy or to other federal agencies. He must have

*Presented at the annual meeting of the Massachusetts Medical Society, May 27, 1942, and as a report to the Council of the Massachusetts Medical Society from the Massachusetts Committee of Procurement and Assignment Service. The members of this committee are: H. M. Clute, J. J. Curley, E. L. Kickham, Dwight O'Hara, W. H. Pulsifer and Reginald Fitz, chairman.

†State director for Massachusetts, Procurement and Assignment Service for Physicians

had a twelve-month internship or its equivalent. He must be a licensed practitioner of medicine.

Experience has demonstrated that young physicians make more effective medical officers than older men. The present Army and Navy needs are for physicians under thirty-six years of age. Those under thirty-six desiring immediate commissions may now write to the Procurement and Assignment Service, 601 Pennsylvania Avenue, N. W., Washington, D. C., or may interview Lieutenant Colonel Alexander Marble at 319 Longwood Avenue, Boston. Those who are qualified will receive proper application forms for commissions in the Army or the Navy. The filling out of the enrollment form does not constitute an application for a commission: the man who wishes to volunteer must, in fact, apply to the proper authorities.

One of the first problems presented to the Massachusetts committee has been to analyze the physician complement of Massachusetts in younger men, to determine those who might best be spared for national service by their civilian communities.

In the State, at present, in round numbers, there are 8000 doctors. Of these, approximately 3300 are less than forty-two years old. Women and foreigners are not eligible for commissions. There are a certain number of young men, too, with physical handicaps so serious that even most liberal standards cannot pass them. Their bearers are hopelessly unfitted to withstand the vicissitudes of Army or Navy life. The exact number of women doctors, foreigners and physically unfit men has not been counted accurately, but it is a fair assumption that about 10 per cent of all young doctors will be disqualified from any form of military service for one or the other of these reasons.

Of the 2970 remaining, a certain number will be absorbed in the necessary work of medical teaching. Obviously, if the practice of medicine is to continue, an uninterrupted procession of students must march through the medical schools, and their pathway of effective medical education must be interfered with as little as possible.

Boston University, Harvard University and Tufts College were asked to submit to the Massachusetts committee a list of their medical faculties, marking each member as an "essential" or "available" teacher. When the first lists were completed, the three deans conferred with the state chairman and agreed to revise their lists for the purpose of retaining as "essential" teachers only those under forty-two who in fact were necessary to a smoothly continuing process of medical education. These three faculties employ, ordinarily, 707 such young teachers. Of this large list, only 148 have been retained as "essential." These essential young men are, in the main, engaged in

teaching the preclinical sciences or in working on research essential to national defense. The medical schools have adopted the policy that good clinical teaching can be conducted very largely by older men. Each school has determined to be understaffed rather than overstaffed with young clinical teachers, and thereby has set a good example for unselfish, patriotic conduct to the rest of the country.

Before the Procurement and Assignment Service had become activated, a certain number of men had already volunteered and had been commissioned; others were in the Medical Reserve Corps or National Guard and were called to active duty. The exact number of such medical officers in Massachusetts has not been ascertained, but from known figures it is estimated that at present at least 300 young physicians already are with the armed forces or are commissioned to go on active duty when called.

The various hospitals that train interns and resident physicians or surgeons have presented an interesting problem. Those approved by the American Medical Association for this purpose were written to and were asked to estimate the minimum number of interns and residents with which they could operate effectively each year. There are two types of hospitals in this group: the state institutions and those privately endowed. The state institutions will require a resident staff of about 100 young physicians and, without much question, will obtain them. The privately endowed institutions, on the other hand, claim to need a staff of 490 interns each year and 180 resident and assistant resident physicians or surgeons.

These figures are of considerable interest. The supply of interns is maintained in large measure by recent graduates of medical schools. The accelerated program of medical education adopted by most of the schools in which classes graduate at nine-month intervals instead of annually will do something to maintain the supply. On the other hand, even under the accelerated program, there are not enough students in the Massachusetts schools to yield more than 350 interns a year. Normally, the necessary extras have come from other than local medical schools or from persons who have accepted repeated internship appointments.

After July 1, nearly all medical students will be commissioned officers in the Army or Navy on graduation, likely to be called to active duty on completion of a year's internship. The chance for a man to experience more than a year's internship will be slight. The entire country offers more internships than can be filled so that the supply of men outside Massachusetts coming to our hospitals will be curtailed. And finally, because of the need for medical officers and the large number

of internships available, it is a reasonable assumption that the Surgeons General will permit students but little free time after graduation in which to begin their hospital appointments. All this means that Massachusetts hospitals face a shortage of interns. Hospitals will be fortunate if they can fill, successfully, two thirds of the appointments that they offer. It appears desirable to suggest to the hospitals approved for intern training that they offer twelve-month appointments, to begin as promptly after the end of each medical school academic year as possible, and to warn them of the possibility of being unable to fill all the appointments offered.

The resident situation is even more precarious. An appreciable number of resident physicians and surgeons have already left hospital posts. The armed forces have argued that any healthy doctor with hospital experience of a year's duration is suitable for military service. Many residents, imbued with a high spirit of patriotism, resigned their posts as quickly as possible after Pearl Harbor.

So long as the present emergency lasts, it is reasonable to assume that it will be hard for hospitals to acquire and hold resident physicians and surgeons. They must be drawn largely from those men who are disqualified physically from more active work or from women. The Massachusetts committee, acting on advice from the Surgeons General, is no longer disposed to regard all residents as "essential" men. A few residents occupying responsible posts in large teaching hospitals may be retained.

There are approximately 200 hospitals in Massachusetts. As has been stated, one of the purposes of the Procurement and Assignment Service is to see to it that the civilian needs for medical care in each community are unhampered. Each hospital has been invited to submit to the committee a list of its staff, each member thereon being classified as "available" or "essential." Up to the present time, returns have been received from nearly two thirds of the hospitals in the State. The figures so assembled from the samples given offer suggestive data.

Of 1187 doctors under forty-two years of age who are above the rank of residents on hospital staffs, 512 (43 per cent) are regarded as "essential" to hospital work; 525 (44 per cent) are "available"; and 150 (13 per cent) are already commissioned or have applied for commissions in the Army or Navy.

These figures enable one to visualize, with reasonable accuracy, the present situation in Massachusetts regarding the procurement and assignment of physicians, which is graphically illustrated in Figure 1. If these figures are even as ap-

proximately correct as they are believed to be, a continuous supply of about 1200 young doctors is necessary to the health and welfare of the citizens of Massachusetts, and there is a pool of about 1800 in which must be determined the ones who can be properly claimed as "essential" in their ci-

FIGURE 1. *Classification of Physicians in Massachusetts Less than Forty-Two Years of Age.*

vilian capacities, and those to be regarded as "available" for military service.

It is to be emphasized that the medical corps of our armed services are comprised of volunteers and not of inducted men.

Up to the present, the names of those who have volunteered since the Procurement and Assignment Service was established have been forwarded from the central office in Washington or from the corps-area chairman to the state chairman, and he, in turn, has forwarded them to the appropriate district committees. The district committees have studied the case of each name submitted to them and have cleared the owner as "available" or "essential." Finally, the state chairman has made certain, before rendering to Washington his final report, that the person under consideration was not an "essential" teacher or hospital-staff member.

This general policy appears sound and seems to give appropriate consideration to each case. To date, 394 names have been cleared in this manner. Of these, 308 (78 per cent) have been deemed "available" for national service.

This plan of managing the medical profession during the present war is still in the experimental stage. Four hundred "clearances," however, seem a reasonable sample from which to take a preliminary account of stock. For this purpose, a population map of Massachusetts* has been constructed in which each county has been arranged in size according to its population (Fig. 2). In each

tors therein declared "available" (Fig. 3). There appears to be remarkable uniformity in the manner in which local committees operate. So far, no single county has been depleted of its young medical men, and the desire to supply medical officers has not outweighed the need to maintain proper oversight of civilian health.

One interesting impression has developed from

FIGURE 2. Population Map of Massachusetts Showing the Distribution of All Physicians and That of Those Declared "Available" by the Procurement and Assignment Service.

county, the total number of doctors has been listed, each dot on the map representing 10 doctors; and finally, in each county the number so far declared "available" by the Procurement and Assignment Service has been set down.

As can be seen, the distribution of doctors throughout the State is relatively uniform, except that Norfolk and Suffolk counties appear somewhat overcrowded medically. Certainly, the total supply of doctors seems ample for some time to come.

That the local committees have worked honestly in analyzing the list of names sent to them is suggested by a tabulation of the medical population of each county and by the number of doc-

this short experience with the Procurement and Assignment Service. The men whose names have been cleared have come from five sources. They have come from Boston University, Harvard University, Tufts College, approved medical schools from outside Massachusetts, and finally, from schools at present not recognized by the Surgeons General, the most important Massachusetts medical school in this category being Middlesex University. Information has been obtained concerning the number of graduates, from these Massachusetts schools, under forty-two years of age and licensed to practice in Massachusetts. These figures have been compared with the number of men from these schools so far cleared by the Massachusetts committee of the Procurement and Assignment Service. The information obtained in this manner

*This map was constructed by Dr. W. L. Aycock, of the Harvard Medical School. The figures for physicians were taken from the 1940 edition of the American Medical Directory.

and illustrated in Figure 4 is of some interest.

The data suggest very pointedly that young physicians from all medical schools are, at present, willing but are in no great haste to offer their services to the country. On the other hand, there

FIGURE 3. The Relation of "Available" and Total Physicians in the Different Counties of Massachusetts.

is no desire among any single group to behave selfishly in times like these. The figures offer additional support to the belief that there are large numbers of young physicians in Massachusetts still potentially available for military service.

To certain persons, one annoying aspect of the method of procedure up to date has been the delay between the date of volunteering, of "clearance" by the Procurement and Assignment Service, and of receipt of commission. To offset this, in Massachusetts, a team under the leadership of Lieutenant Colonel Alexander Marble has been established by the Army with power to commission, immediately, men cleared as "available" by the Procurement and Assignment Service. This means that henceforth the commissioning of our medical officers will be greatly accelerated and that annoying delays will be eliminated.

This, in brief, has been the experience of the Procurement and Assignment Service for Physicians in Massachusetts during the first three

months of its existence. On the whole, the method adopted for enrolling medical men in national service seems workable, fair and considerate. The results are already promising and point to the fundamental value of a democratic way of building up a large volunteer medical corps.

When one looks to the future, it is obvious that there are many young doctors in Massachusetts who should enter military service as quickly as possible. Young physicians, especially those in Suffolk and Norfolk counties, where the medical population is so dense, should be enrolled in large numbers. On the other hand, all local committees must continue to see that no region or town in the State is depleted of its young men in the desire to supply medical officers. Civilian needs must not be forgotten.

Most of these young men already declared "available" by their hospitals may well be expected to take up the cudgels of war at once. "Essential" young men will soon be declared "available" to

FIGURE 4. The Source of Young Physicians in Massachusetts.

The columns represent the numbers of graduates from 1926 to 1941 who are practicing in Massachusetts, the solid portions showing the numbers of those already investigated by the Procurement and Assignment Service. The total number of graduates from medical schools outside Massachusetts is not known.

volunteer, if need be, and as hospitals become adjusted to the view that older men on their staffs are still capable of doing more than a full day's work. The health of the Commonwealth need not suffer from this plan, for there are more than enough doctors to go round. All physicians of Massachusetts will contribute more than their share in doing the work that must be done.

319 Longwood Avenue

CIVILIAN MEDICAL DEFENSE IN MASSACHUSETTS*

ELLIOTT C CUTLER, MD†

BOSTON

THE Committee on Public Safety welcomes this opportunity to thank the physicians of Massachusetts for their fine co operation and their loyal and generous assistance in organizing for the care of the civilian population injured by enemy action. Up to the time of Pearl Harbor, there were two almost equally divided opinions concerning the necessity for this effort. In fact, the group who thought such efforts were silly and wasteful were the more vociferous. The injuries sustained by civilians in Hawaii and Tokyo had a salutary effect in behalf of those who, although they may not expect bombing, believe that the best defense against it is suitable preparation. One should remember that it has repeatedly been stated in England that gas was not used there because England was better prepared for this dilemma than Germany. Preparation is the best defense.

We here do not need to have an elaborate organization or spend the public funds in setting aside great numbers of empty beds. Sir Wilson Jameson,‡ chief medical officer of the British Ministry of Health, said last winter while he was here, "The tremendous anticipated casualties never did materialize, and it was found that to try to run a service of this kind on a full time basis was not satisfactory." What we need is a simple and mobile organization of our entire facilities. Moreover, in considering any organization, we must conserve trained professional personnel and use, preferably, persons over forty-five years of age or those with physical disabilities that prevent active service with the armed forces.

Civilian medical defense in Massachusetts began with the establishment of the Committee on Public Safety in September, 1940. It was the hope of the Medical Division that a system could be set up that was mobile so that assistance could be obtained from many communities and sent to a distant community if the need proved great enough. It was further hoped that expenditure of public funds could be kept down by avoidance of the permanent dispensary construction that was undertaken in London, and that a minimum of professional personnel could be utilized.

The State Central Committee is composed of the Medical Executive Committee and various sub-

committees, all of which comprise representatives covering the Massachusetts Department of Public Health, the hospitals, the dentists, the nursing organizations, the American Red Cross, the medical examiners of the Commonwealth and the pharmacists. Indeed, all interests that might give aid should disaster occur have their share in this setup. Specialists in gas decontamination and persons who aid in the proper relation of the Medical Division to the Protection Division and Evacuation Division sit on this central board.

The function of the Central Committee was to set up a system that could be utilized throughout the Commonwealth in small rural areas as well as in the large urban centers and to assist the local communities in obtaining the necessary equipment for the task. To assist the committee, there are, in each of the nine regions into which the State has been divided, regional medical heads, who have a group of deputies to help them. These deputies represent more intimately the members of the district societies of the Massachusetts Medical Society, the dentists and the hospital superintendents. They assist directly in stimulating the 351 communities to complete their organizations and give them practice. They help in the distribution of supplies and in the proper blacking out and organization of hospitals. In each of the district warning centers, which are the nerve centers of the information system, a deputy medical head must be at hand to give the controller expert information on medical matters. Information concerning the number of ambulances, first-aid posts and vacant hospital beds in that area must be available. Should these be used up, the deputy medical head must know where others can be obtained. In fact, these regional setups should be so complete that, if the state office at 18 Tremont Street, Boston, were wiped out, relief to the citizens would go on in a competent and satisfactory manner.

The plan now in use in the 351 communities of the Commonwealth puts full authority and responsibility for the setting up of medical assistance on the shoulders of the local chief medical officer. The plan is as follows: in each community, there are four parts to the medical services—first aid parties, mobile medical first-aid posts, transportation facilities and hospitals (Fig. 1).

*Presented at the annual meeting of the Massachusetts Medical Society, Boston May 26, 1942.

†Voseley Professor of Surgery Harvard Medical School, surgeon in chief Peter Bent Brigham Hospital, director Medical Division Massachusetts Committee on Public Safety.

‡Jameson Sir Wilson *Hospitals in England Today*, 14 pp. New York: Hospital Council of Greater New York, 1941.

A *first-aid party* consists of six lay people trained in first aid who carry on their persons suitable first-aid equipment. They are sent out to the scene of an incident, where they apply temporary dressings and first aid, guide the walking wounded and carry the stretcher cases to the physicians and nurses in the medical first-aid posts.

A *mobile medical first-aid post* is a group of physicians, nurses and lay people trained in first aid who set up in a building an incident dressing station. There are two doctors and two nurses so that one professional group can take charge of the stretcher cases, and the other group the walking wounded. No attempt should be made to carry out surgery at this point other than the ligation of a bleeding vessel or the control of some dire catastrophe. At such posts, hot drinks should be served by mobile canteens, suitable dressings should be added to the dressings already applied, splints should be readjusted or applied, and morphine should be administered for comfort. The stay in a first-aid post should be minimum, since the critical point in the recovery of injured people is proper surgical care in a hospital.

Transportation facilities. After preliminary dressings and the splinting of fractures have been carried out in the first-aid post, the injured people are taken by some kind of vehicle (and anything that moves on wheels from a sand truck to a beach wagon or a sedan will do) to the nearest emergency hospital.

Hospitals. At the hospital, provisions must be made for one-way traffic. The walking wounded and stretcher cases should be separated and looked after by separate teams. The hospitals must be properly blacked out—at least the admitting rooms, the x-ray departments and the operating rooms. They should be prepared, from now on, to send home convalescent people and noncritically ill medical patients, to make room for casualties, and the hospital staffs must be organized into eight-hour or twelve-hour shifts so that the professional care may go on continuously. We have listed 95 hospitals that have more than 50 beds and are not special hospitals as places suitable for such work, but in a grave emergency, any hospital must be ready to function for this purpose.

In the event of continued bombing, casualty cases and others will be evacuated from metropolitan areas to rural hospitals in the country that have been called "*base hospitals*." At present, some 6000 beds are available in rural state institutions for this purpose. The staffs of these base hospitals will need to be supplemented, and the Medical Division has been given the privilege of nominating certain physicians, preferably over the age of forty-five, for reserve commissions in the United States Public Health Service. It is expected that such reserve officers, when called to active duty, will be ready to leave their homes and practice, put on uniforms and go to service as directed.

The medical equipment and the stretchers, blankets and splints for the desired number of first-aid parties and medical first-aid posts are now being distributed on the basis of two parties and one post per 10,000 inhabitants. Massachusetts, at this ratio of distribution, will require 438 posts. However, since small communities cannot be divided at that ratio, we shall probably end up with about 1000 first-aid posts. The gauze equipment for all these posts has already been provided by the Boston Metropolitan Chapter of the American Red Cross, sterilized at the Peter Bent Brig-

ham Hospital, and delivered to the communities. The pharmaceutical supplies, including morphine, alcohol and other drugs, have been donated by the Massachusetts Pharmaceutical Association and have been distributed to the communities.

Lest anyone should think getting material ready for civilian defense is a little job, imagine the task of dividing 140 pounds of sulfanilamide into 23,000 3-gram lots! In addition to our own labors, we have assembled 65,000 air-raid warden's belts, with their equipment, for the Protection Division. The belt material for the first-aid parties was given by the New England Rainwear Manufacturing Company, and the material was stitched into belts by the Ladies Garment Workers Union, who gave 18,000 hours of free labor. We hope, eventually, to acquire additional medical supplies, splints, stretchers, blankets and so forth from the federal government in Washington, but thus far, all supplies and equipment and training have been arranged locally by the Medical Division of the Committee on Public Safety. (It may seem peculiar to some of you that the federal government has not taken a greater interest in the protection and care of injured citizens, since war is obviously a general governmental undertaking, but all of us must recognize the serious demands on the Government at this time. Criticism will not help, and until each citizen is devoting a part of his time daily to the national welfare, he can scarcely criticize others. Remember that this civilian defense is a voluntary effort and, therefore, perhaps somewhat protected from the chronic "grouser.") Many generous citizens have given time and funds, and an attempt has been made to keep the expenditure of tax funds as low as possible. An especially welcome gift was the receipt of twelve complete field sets (consisting of two boxes of bandages, splints, instruments and drugs) suitable for equipping a medical first-aid post from the Medical and Surgical Relief Committee of America, which has its headquarters in New York City. These sets have been distributed either to vulnerable areas, to areas that deserve assistance because of their generous labors, a reward for virtue or to areas where the expense of equipping such necessary units was beyond local means. Furthermore, through the efforts of the Massachusetts Pharmaceutical Association, 978 emergency medical depots, have been established throughout the state.

The functioning of first-aid parties and posts is similar for all communities (Fig. 1). Information of damage will reach the chief air-raid warden of every report center in that area. The chief medical officer will then send to the incident the proper number of first-aid parties and posts in vehicles, later to be used to transport the wounded. From the first-aid posts, the injured will go to

the nearest hospital, whence, after an interchange of blankets and splints, the ambulances will return to the first-aid posts.

The Medical Division has further responsibilities such as the care of persons who are gassed. In this responsibility are two groups. The first includes those simply gassed but uninjured. Such persons will be taken to a gas decontamination center, where they will be denuded of their cloth-

simple gas decontamination annex, which must have at least two rooms separated by a gas lock. There must be one area in which to rid a gassed person of contaminated clothing and another area in which to decontaminate the victim by washing before he is admitted to the hospital for further surgical care.

A particularly happy phase of the work concerns our relations with the United States Public Health Service. Through their generosity, two members of the Medical Division will hold commissions in that federal branch. We are further authorized, as previously stated, to set up reserve affiliated units in the Public Health Service. In addition, we can utilize certain of our colleagues as consultants in the United States Public Health Service should the magnitude of the occasion necessitate such service. Another activity has been the gift to the Commonwealth of large funds to be invested in the establishment of blood banks. These will serve not only for the military period but also as a permanent contribution to better medical care in this state. Finally, through this same source, the cost of the care of civilians injured by enemy action will be borne by the federal government, including those injured by sabotage, in blackouts and from direct enemy action by combat forces.

Another essential relation is that to the Evacuation Division. In the coastal areas, this division's activities may be of the greatest moment, either because of enemy action or because the military commanders order the evacuation of seacoast districts. The movement of large masses of the population has been planned for, and in the Evacuation Division there is a medical group, since the same diseases and disorders will go on whether there is war or peace. To conserve the already reduced medical personnel of the State so far as possible, we have frequently utilized physicians for work in both divisions. We have also made arrangements with the Evacuation Division that, should evacuees be so ill as to require hospitalization, they will be turned back to the Medical Division; thus, the establishment of two medical groups to deal with the hospital problem will be avoided.

We still need more first-aid party members and more people trained in first aid to serve in the first-aid posts and as ambulance drivers. The response of physicians and dentists to this effort has been entirely gratifying and satisfactory.

It would be invidious for me to mention any personal names before our colleagues. I have always told His Excellency, Governor Saltonstall, that he need have no fears about the medical aspect of civilian defense, that everywhere in the Commonwealth doctors were happy to help out. It is

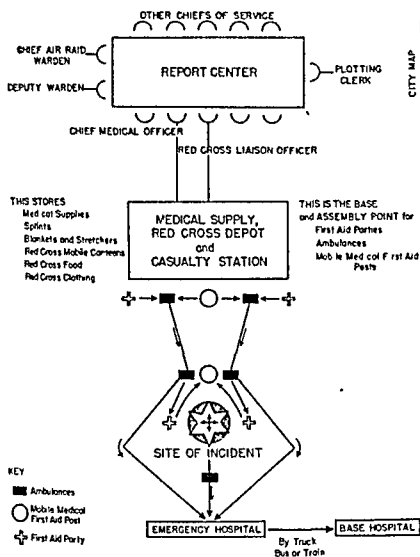

FIGURE 1 Community Organization at and from the Report Center.

ing, thoroughly washed for decontamination, and finally given fresh clothing supplied by the Commonwealth. The intricacy of such a setup, with its gas locks, decontamination and ventilation, need not be gone into here. The Commonwealth has set up an ideal center of this type in the basement of the former Huntington Hospital. This phase of our activities has been under the direction of two physicians, who have not only been willing to go away to acquire an education in this field but also have, in turn, given several courses to doctors of the Commonwealth, so that all communities may be thoroughly instructed in this vital matter. Such decontamination centers should be set up at the rate of one per 100,000 inhabitants. A different handling of patients must be followed when one considers the person who is both injured and gassed. This requires the organization, in the admitting section of each hospital, of a very

now my privilege, however, to thank publicly, though anonymously, those of your colleagues who have shared together in this great effort. It has robbed many of your friends of sleep and income; it has kept them working late into the night when others were at theaters. But it has been a job done for the good of our people, and I congratulate the medical profession for complete and totally unselfish devotion to the common good. The time has now arrived when new efforts are required. The American people, who are naturally optimistic and already misled by unjustifiably hopeful news on the radio and in our newspapers, are beginning to think that we are winning the war and that the end is in sight. This is now leading to defection in the ranks of civilian defense. Air-raid wardens

are less conscious of their tasks, and some are resigning. The cold facts are that we have not won a battle yet. In England, civilians were not bombed until the country had been at war eleven months. Now, as never before, we of the medical profession must stand as a power to keep this essential activity alive and ready for the emergency. We cannot say when disaster will come, any more than the residents of Pearl Harbor or Tokyo could, but we must not underestimate our enemy and we must be prepared lest the women and children of this commonwealth suffer through our carelessness. Every physician who is not serving his country in the military forces should devote a part of each day to this grave and vital responsibility.

THE PHYSICIAN'S ROLE IN FIRST AID*

A. WILLIAM REGGIO, M.D.†

BOSTON

IT is difficult to understand why it took Pearl Harbor to make the medical profession take an interest in first aid, and yet, on the other hand, it is not so difficult. If one faces the question squarely and honestly, one finds two outstanding reasons for this lack of interest on the part of at least 95 per cent of the medical profession: the great majority of medical schools, until recently, have completely omitted the subject of first aid from their courses of study; and physicians are consequently unfamiliar with—and, one might say, ignorant concerning—the subject matter and methods of first aid.

Gradually, physicians are discovering that first aid really amounts to something—that it is not merely childish nonsense or an attempt to turn laymen into doctors in a few short lessons. They are also finding out that the layman expects any physician to be able not only to render first aid in the best and most approved fashion but also to teach the subject to a class at a moment's notice.

Unfortunately, although physicians can diagnose the most obscure diseases and treat the most difficult conditions, when all hospital facilities are available, they are completely at a loss when faced with the problem of administering first aid or transporting a victim to a hospital without the usual equipment.

First aid is not, and must not be considered, a matter too elementary for the serious consideration and assimilation of every physician.

The training of laymen in first aid was begun by the American Red Cross in 1910, when the first class was taught and the first certificates issued, denoting the successful completion of this first course. It took twenty-five years to reach the first million certificates—from 1910 to 1935. Then, for the second million, it took four years, that is, from 1935 to 1939, and the third million from 1939 to 1941, or two years more. During the past year, the fourth million was completed.

In a personal communication, I have just been informed that during the month of March, 1942, Washington issued about 352,000 standard certificates and was still behind in issuing the total number requested. At this rate, if it keeps up,—and it seems to be doing so,—there will be over 4,000,000 standard certificates issued for this year alone. To emphasize this once more: thirty-one years, 1910 to 1941, 4,000,000 certificates; in all probability in this one year, 4,000,000 certificates.

Accordingly, the increased interest shown by the medical profession in first aid, as taught by the American Red Cross, is most encouraging. In January of this year, a short eight-hour course was given to a group of one hundred and twenty-five physicians from the different district societies so that they could transmit this knowledge to others and teach laymen in standard first aid. It was quite evident that all these doctors were pleasantly surprised at what they learned of a subject new to them and that they definitely enjoyed the sessions and profited by them. Since then, the number of doctors asking for instruction in the mechanics of first aid has been most gratifying and encouraging.

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1942.

†Deputy medical director, Medical Division, Massachusetts Committee on Public Safety.

I shall not mention names, but ten or fifteen doctors in and around Boston have been giving many hours of their time to teaching not only laymen but also physicians and dentists so that they, in turn, could adequately instruct classes of laymen in the standard course. This has not been an easy undertaking, and they are to be congratulated for their perseverance and untiring efforts in doing this job and doing it well.

At long last, a standard course in first aid is being taught to practically all the students at Boston University, Harvard, Tufts and Middlesex medical schools. A large number of these young men have already received certificates as instructors in first aid, and many more are continuing toward that end. The students have taken up this subject with marked enthusiasm, and a number of them believe that the standard course in first aid should be a required part of the first-year curriculum. It is to be hoped that this desire on the part of the medical students will be heeded by the powers that be.

A grievance that it is in the province and power of the profession to dispel is the thoughtless and destructive criticism of first aid still being made by some physicians. Destructive criticism is vicious, constructive criticism is always welcome. It is less than it was a few months ago, but it is still going on and is doing harm by causing confusion in the minds of lay instructors concerning what they are teaching in their courses.

Two main topics are in dispute, namely, the use of iodine in wounds, and traction splinting in fractures.

The application of iodine in a wound is taught in the *First Aid Text Book* of the American Red Cross. Every effort is being made to have this teaching changed so that iodine—in mild, medium or full strength, it makes no difference—will not be used in any wound, and a revision of the text to that effect is advocated.

Traction splinting of fractures. Many physicians still do not appreciate the value of immobilizing fractures before the victims are moved from the scene of an accident to a hospital. The American Red Cross textbook teaches this, and every man familiar with and accustomed to treating fractures agrees with this recommendation. During World War I, the value of this method of transporting patients with fractures, particularly of the femur, from the field to the hospital was amply proved by the facts that before such splinting was instituted the mortality in this type of fracture was about 60 per cent and that after traction splinting was used the mortality dropped to about 25 per cent. This in itself indicates the benefit of this method, to any thinking person. Yet some doctors still oppose or fail to recognize the necessity of this precaution

before moving victims with fractures. Although many laymen who have received certificates for having passed the examination in standard first aid are not capable or willing to apply this method in an emergency, at least they will be able to prevent others from doing the wrong thing to a victim, because they know what should not be done. For example, not very long ago, a victim with a broken lower leg was being prepared for splinting by a layman trained in first aid when a doctor arrived on the scene. The layman naturally gave way to the doctor, who, after some uncomplimentary remarks on the layman's efforts, proceeded to pick up the victim and place him in his car, making the fracture compound in the process. An occurrence of this kind is inexcusable, and should not be countenanced by the medical profession as a body. How can one possibly expect the layman to respect the teaching of first aid when members of the profession so flagrantly disregard the most elementary principles in the care of the injured?

It is readily admitted that certain first-aid measures, as taught to laymen, seem inadequate in the eyes of some medical men, but one must not forget that the layman is not a physician and moreover, that he is not qualified, nor can he be expected, to use some measures that a medical man might be justified in using.

First aid is merely a way for the layman "to hold the fort" without further increasing the damage already done until the services of a doctor can be obtained. Passive inactivity on the part of such a first-aid worker is preferable to active inadequacy, and that is one of the principles taught in first aid. It is better, of course, to do nothing than to do the wrong thing. If the victim is merely left where he is and kept warm until help is available, many a life may be saved.

To play a part in first aid, the doctor must know something about it. Since many physicians are already affiliated with casualty units or mobile first-aid posts and will have working under their direction a personnel trained in first aid, they should be familiar enough with their duties to train these workers in practice sessions, so that in the event of an emergency the unit can function to the best possible advantage.

These people will ask questions that must be answered correctly in the layman's language. One cannot do this unless one can speak the same first-aid language as the personnel. The first-aid workers should not be told to do things that they have not been taught in their courses, and to avoid this confusion it behooves physicians to familiarize themselves with what the workers have been taught.

The commanding medical officer in charge of these mobile units must be able to train his per-

sonnel in stretcher drill. This it will be difficult for him to do unless he has first learned it himself. One hears complaints from many medical men in these units that they cannot obtain a sufficient number of people trained in first aid to act on their units and in the first-aid parties. The demand for instruction is heavy, and the number of lay instructors available is barely adequate to handle the number of applicants.

Hence, if the doctors themselves will instruct the people whom they will have working on their units, the number of trained workers will rapidly increase.

All this, of course, means *work* on the part of the doctors, but as this present emergency progresses, the amount of work will naturally increase; physicians must work even harder than they are doing already, and train their personnel. No one knows when some of the mobile first-aid units will be called on to function as the result of enemy action, and they will be expected to handle the situation adequately. The men in charge of these units and their organization are working day and night to be prepared and ready at a moment's notice. It is imperative that these mobile units hold practice sessions to become accustomed to working together under the tension and confusion that are bound to result if the emergency arises suddenly.

A tremendous responsibility is borne by the medical profession. The public looks to physicians to take care of them in the event of enemy action. Whence or how this will come is not known, but one certainty is that the emergency *will* arise and that physicians must be ready to cope with it and render the best possible care to the injured.

As more doctors leave civil practice to enter the Army or Navy, increased work is thrown onto those remaining behind. Mobile medical units already formed must find new men to replace the ones called to active duty. Such new men will have to be trained for this first-aid work, and it will help tremendously if all physicians look ahead even farther and acquaint themselves with what is going on in their communities and find out where they will be most needed and best fitted to serve.

Everyone should be familiar with the measures that are to be carried out at the medical first-aid posts or casualty stations throughout the State, and with the measures to be taken in the event of chemical or gas warfare as affecting the civilian population.

When the emergency actually arises, it will be too late to learn, and there has already been enough of "too little and too late." We cannot afford any more delays. We *must* anticipate the next play and be ready to checkmate it from the very start.

At the first-aid casualty stations, which will be set up as near the scene of an incident as possible, only the most essential first aid will be rendered to the casualties. Any major procedures will be carried out by the emergency teams at the hospitals to which victims are taken by ambulances from these medical posts. It is therefore necessary for the physicians comprising the personnel of these posts to be thoroughly familiar with such measures as the splinting of fractures for safe transportation.

They must be able to guide their first-aid helpers in the application of these splints, whether for immobilization or for traction. The control of hemorrhage is vital, and decisions concerning the application of a tourniquet must be made rapidly; correct application is essential and will be the responsibility of the physician in charge.

His familiarity with emergency procedures is vital, since he is the one who must keep calm and cool so that his assistants will not become panicky or disorganized in the face of conditions of suffering and injury that they will encounter, in actual fact instead of in theory, during their course of instruction. The physician is accustomed to sights and sounds that will be entirely new to the layman; it will be his responsibility to keep things running smoothly.

He must be familiar with artificial respiration, which is not so easy and simple as it sounds. Practice and experience in its administration are necessary before it can be done correctly and efficiently. Burns will have to be taken care of and quickly sized up as to severity, and appropriate first aid given with the materials at hand before the cases are sent to the hospital. Morphine must be given in sufficient dosage to quiet a victim during transportation. Judgment regarding the size of the dose is necessary to make sure that it is large enough to accomplish its purpose. Shock treatment of an elementary kind must be given to tide over the victim until he receives further treatment at the hospital. Major and minor wounds must be evaluated rapidly, and the danger of minimizing an injury must be avoided — especially in head injuries is this danger very great, as, of course, everyone knows. Underestimating the potential complications in head injuries may be fatal, whereas a more mature appreciation of possible underlying injury may make a tremendous difference. This is well known, but is worth emphasis.

* * *

To conclude, I again emphasize the importance of the physician's role in first aid — the layman looks to us for guidance and instruction. How can we possibly help him to the best advantage if we, ourselves, are not thoroughly familiar with this subject?

MEDICAL-SCHOOL PLANS FOR THE EMERGENCY*

BENNETT F. AVERY, M.D.†

BOSTON

AT a time when our very survival depends on an immediate all-out military effort, any civilian activity whatsoever must justify its right to continue. We have suddenly awakened to the startling fact that one plane or gun or ship now is worth ten next year and a hundred the year after. We are newly aroused to the necessity of throwing everything we have into ensuring that we do not lose the war this summer, and at the same time we are filled with the dawning hope that if we work hard enough and move fast enough we may achieve victory in 1942.

Nothing can have precedence over the priority that we must accord to the military effort, and it is in the light of this fact that we should examine the situation regarding medical education. We should consider not only the effect of the war on the medical schools but also the contribution the schools are making or can make toward winning the war.

It is now clear that, of the 155,000 practicing physicians in the country, 30,000 will soon be in the medical corps of the Army and Navy. It is conceivable that in a prolonged war this number might even be doubled. The effect, as you all know, is already being acutely felt in communities and hospitals. It will be far worse before it gets better. Every available young physician will soon be in active service, and if the war should take longer to win than we hope, there may not be enough who are physically fit to meet the needs of the military forces.

The inescapable conclusion is that it is the duty of the medical schools not only to continue in operation but to train capacity classes as rapidly as is consistent with the maintenance of high standards. This was early recognized by the three schools in Massachusetts, and on December 29, 1941, Tufts College Medical School, Harvard Medical School and Boston University School of Medicine issued a joint announcement to the effect that beginning July 1, 1942, summer vacations were to be eliminated in favor of a program of continuous operation.

To consider the many problems involved in the adoption of accelerated schedules, a special meeting of the Association of American Medical Colleges was held on February 14 of this year in connection

with the Annual Congress on Medical Education and Licensure of the American Medical Association. The program was approved in principle for those schools that could adopt it without sacrificing teaching standards. Resolutions were passed at this time by the Council on Medical Education and Hospitals of the American Medical Association and by the Federation of State Medical Boards of the United States supporting the action taken.

The result has been that up to the present fifty-nine of the sixty-seven four-year medical schools in the United States have adopted an accelerated schedule, and four more are expecting to adopt one. In most cases, classes are to be admitted every nine months, beginning about July 1, 1942, and the four academic years will be completed in three calendar years. This means a 33 per cent speed-up in the production of physicians, showing its first fruits next February and March, when five thousand doctors will graduate three months earlier than normal. The following January, another five thousand will graduate six months early, and in September, 1944, a third five thousand will graduate nine months before the regular date. The climax will come at the end of three years, when a class of five thousand will finish a year ahead of the normal time.

The difficulties involved are great, but are no worse than those attending most phases of the war effort. Hospitals, faced with providing internships at nine-month intervals, have proposed making their old interns who have served nine months into junior residents for their remaining three months, to supervise the newcomers. The expected dearth of residents will make this feasible.

In seven states, the medical-practice acts require a recognized medical course to be given in four different calendar years, but amendatory legislation is under way or expected. In five other states, the law may be liberally construed as it stands. In the remainder, the question is for the examining board or other state approving agency to decide, and in view of the action taken by the Federation of State Medical Boards, no trouble is anticipated.

Almost universal action on the part of pre-medical colleges in adopting an accelerated schedule of their own will probably maintain a full supply of applicants for admission at the irregular nine-month intervals. My own observation has been that most applicants for places in the incoming class of next March expect to complete a full year's

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1942.

†Dean and Waterhouse Professor of Anatomy, Boston University School of Medicine.

work between now and then, by taking a double summer session in addition to the regular fall semester.

The substitution of a short rest period between each academic year in place of the long summer vacation raised the question of financial aid to students who were formerly dependent on summer earnings. The generous action of the W. K. Kellogg Foundation in making available loan or scholarship funds to one hundred and fifty medical, dental, public-health and nursing schools in the United States and Canada has helped greatly in meeting this urgent need, and private donors have been generous. It may even be that a government loan fund will be established for succeeding years.

There is still the question how well the health of the students will stand the strain of continuous cycles of eight months of work followed by only one month of vacation, but plans are under way for an unusually careful watch over their physical condition. It is hoped that breakdowns due to tuberculosis or mental or nervous fatigue will not increase unduly.

The War Department, the Navy Department and the Selective Service System have recognized the need for maintaining a constant or increasing flow of graduates from the medical schools by deferring students in good standing almost without exception. All medical students and even those accepted as members of the next incoming class are now eligible for commissions as provisional ensigns in the Naval Reserve or as second lieutenants in the Medical Administrative Corps of the Army. In the latter event, not even a physical examination is required. All students commissioned are assigned to the study of medicine until they shall have completed their course and one year of internship.

So far as the faculties are concerned, the situation is difficult. Every school has lost large numbers of its younger staff members, but an effort has been made by the Procurement and Assignment Service to leave key men who are essential to teaching. Those remaining are carrying increased loads because of the smaller staff and accelerated schedule, with resultant sacrifice of research and vacation time. Even so, throughout the country, numerous members of the medical-school faculties are carrying on full-time or part-time research on special war problems, at the request of the National Research Council.

The teaching of military medicine has been given careful consideration, and proposals have been put forward by a special committee of the Association of American Medical Colleges, composed of Dr. Edwin P. Lehman, chairman, Dr. Currier McEwen and Dr. H. S. Mustard. It is

suggested that, except in schools where a reserve-officers training corps is already established, there be no attempt to teach the organizational aspects of military medicine to undergraduates, unless it is for a brief course of orientation lectures.

It does seem desirable, however, that beginning in July, the first-year and second-year students who have not had first-aid training be given at least a twelve-hour course of lectures and practical work. Tropical medicine should be stressed in courses in parasitology and medicine, or even as a separate course in the clinical years. Discussions are now under way for the establishment of such a course as a co-operative effort of the three medical schools in Boston.

To quote the report of the committee:

The necessity for stressing certain subjects of the professional aspects of military medicine within the framework of the present curriculum is recognized. These subjects include the following:

- Shock and blood substitutes
- Soft tissue wounds (including débridement)
- Fractures
- Burns
- Frost-bite
- Sanitation
- Control of communicable disease
- Prophylaxis and treatment of venereal disease
- Cardiovascular disease
- Fatigue states
- Anoxemia
- Compression and decompression
- Aeroembolism
- The physiology of high altitudes and dive-bombing
- Visual adjustments under war conditions
- Poison gases
- Industrial poisons
- Common psychiatric conditions, including modified peptic ulcer syndrome and effort syndrome
- Dermatoses and insect bites

It is recommended that a special course on the professional aspect of military medicine be given to fourth-year students, to include any material listed which has not been previously given and any new material developing as the result of present war experience, such as the newer treatment of burns, the developments of sulfonamide therapy, immersion foot, blast injuries, renal failure of crush injuries, etc.

Even the faint possibility that we may suddenly need to evacuate certain of the medical schools that are located near the seacoast to safer districts inland has been considered. Tentative plans are being laid for removal to districts offering facilities not only for the schools but for the hospitals used in clinical teaching. Any possible arrangement would be far from ideal, but even though we confidently expect that no one will have to move, it seems best to be prepared, for once.

* * *

In conclusion, let me say that once again the medical profession has shown itself to be one of

the most patriotic and foresighted groups in the country. There seems to be no tendency for a brass-hat regime to obstruct swift and decisive action,

and every medical school in the country is making every possible contribution to the war effort
80 East Concord Street

HOSPITAL PREPAREDNESS*

CHARLES F. WILINSKY, M.D.†

BOSTON

THE country is at war. The long accepted theory of safety and protection afforded by distance has been thoroughly shattered, and today the Atlantic and the Pacific oceans are no longer the protective barriers they were so long believed to be. It has been wisely concluded, therefore, that the whole country must be thoroughly organized for the defense of its population.

Much has been said and a great deal written about the place of the hospital in civilian defense. It requires neither particularly keen vision nor vivid imagination to appreciate in its fullest form the vital part that hospitals will be obliged to play in the drama of life and death that sabotage and war, if brought to these shores, will produce.

Modern warfare exacts a tragic toll, not only in a high percentage of deaths resulting from demolition and incendiary bombs, but also in serious injuries, whose treatment requires a high quality of surgical skill.

To meet these possible needs, the Medical Division of the Office of Civilian Defense was created in Washington and placed under the able direction of Dr. George Biehr. The necessity for the formation of state units was urged, and Massachusetts, in keeping with the richness of its traditions in the field of social consciousness and human welfare, was in the forefront of this essential development. We were particularly fortunate in the sacrificing willingness of Dr. Elhott C. Cutler to give so much devotion to the office of director of the Medical Division of the Massachusetts Committee on Public Safety.

Others who have spoken on this program have described the organization of the medical services, with their mobile units, which include physicians and other essential personnel. The establishment of first aid posts near the scene of the incident, as well as medical depots and casualty stations, has been described. Fitting emphasis has been placed on the type of essential organization for the proper functioning of the groups mentioned above, and the services they are expected to render.

It is pertinent to call attention to a certain variance in the functioning plan for medical services in Massachusetts, as contrasted with the recommendations of the Medical Division of the Office of Civilian Defense in Washington. The plan of the latter includes the organization of medical field services from the nonsurgical resident staffs in hospitals, whenever possible. Among the important justifications claimed for this plan are the speed of mobilization and the economy of manpower. The plan in Massachusetts, for which Doctor Cutler is responsible, is built on the premise that hospitals should keep their staffs intact, to care for the injured brought to their doors. The medical field services are to be rendered by practitioners of medicine, recruited in the main from the areas in which they practice or reside and in which they are expected to serve at the time of the emergency.

In the planned organization of medical services, it is readily recognized that emergency hospitals must be made available for the care of the more seriously injured. Nearly one hundred hospitals in Massachusetts are intended to serve as emergency hospitals and are closely linked with their local civilian-defense organizations.

One could devote many pages to the specific recommendations that have been presented for the physical protection of hospitals, including buildings, personnel and patients. However, various factors intervene that must receive careful consideration in the development of local plans. It is, nevertheless, possible to agree on certain objectives, which may be considered the minimum goal of all hospitals.

Protection of Physical Property

The first objective is adequate protection of the physical property of the hospital against damage caused by sabotage, explosion, demolition and incendiary bombs, fires and so forth. This protection can best be accomplished by the installation and maintenance of adequate blackout facilities; adequate protection against fire, organization for necessary emergency repairs to the hospital structure, including possible damage to heat, light, water, power, structural damage and so forth,

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1949.

†Lecturer, Department of Biology and Public Health, Massachusetts Institute of Technology; executive director, Beth Israel Hospital; deputy health commissioner, City of Boston.

and the necessary protective mechanisms for safeguarding patients and personnel, including the organization of rescue squads, provision for air-raid shelters and so forth.

The maintenance of blackout facilities involves the expenditure of funds for blackout material and the cost of installations.

Protection against fires caused by sabotage or incendiary bombing compels the organization and drilling of fire squads recruited from employees as well as volunteers. A carefully selected fire warden trained particularly in the art of handling incendiary bombs will in turn impart this knowledge to spotters and fire fighters. The need of constant watchfulness is a major factor in protection against and control of fires.

The maintenance department of the hospital must concern itself with the problem of emergency lighting and particular protection of the telephone service, water supplies and the power and heating plants. The purchase of auxiliary equipment to meet these needs in the emergency is a justifiable expenditure.

An adequate amount of essential supplies must be provided, and it is strategically sound to store these supplies in several places in the hospital, rather than to expose a concentrated supply to the hazard of destruction. Safe storage should be provided for alcohol, ether and other chemicals. A census has been taken of radium owned by Boston hospitals, and advice given regarding safe storage.

The safety of patients and personnel should be given primary consideration. None of the methods suggested for the protection of glass, including windows and skylights, can be considered foolproof. Wire netting, cloth and beaver board are but some of the suggestions. It is, of course, logical that at the time of bombing, patients and others be moved away from proximity to glass windows. Corridors appear as reasonable shelters as any other places that have been suggested.

Included in the mobile-unit organization radiating out of every medical depot are Red Cross ambulances and, when necessary, other vehicles provided by the chief medical officer. These will be used for the transportation of patients to hospitals on orders of the physician in charge of the first-aid post.

Care of Casualties

The second objective, the development and maintenance of facilities for the prompt care of casualties, must include adequate space and a well-organized plan for the reception of the injured, and the exercise of proper judgment concerning the disposition to be made of the victims, in accordance with the degree of the injury, and their needs.

This calls for continuous, essential, well-equipped professional service, including the availability of surgeons, nurses, anesthetists, x-ray and laboratory units, transfusion facilities and shock teams. It is essential to re-emphasize the need of personnel on a twenty-four-hour basis.

One cannot overestimate the value of the prompt and sound sorting, by the triage officer, of the injured brought to the hospital, and the careful recording of the disposition of the cases. The skillful surgeon assumes a serious responsibility for the making of important decisions concerning: disposition of the walking wounded; patients in need of immediate surgical attention in the operating room; treatment for shock; need of x-ray diagnosis of fracture, foreign objects and so forth; treatment of burns; fracture service; and specialized services, including the orthopedic, eye, nose and throat, neurosurgery, faciomaxillary and those for the treatment of serious chest and abdominal wounds. Doctor Cutler wisely advises constant watchfulness, so that the secondary needs of casualties sent first to the above units may be adequately met. Leadership and authority should be vested in the executive director of the hospital.

Plans must be developed in every community, to assure a working knowledge of the number of available beds for the care of casualties. In communities with a number of hospitals, a central registry of hospital beds must be established, to which the regional and chief medical officers, as well as hospital authorities, will have access for necessary information. At the time of the incident, the medical officer or his deputy will be at the control center, and in possession of this essential information. He will be in periodic touch with hospitals and the deputy medical officer in charge of medical depots and their mobile units. It will be possible, through this constant vigilance, to send victims promptly to the emergency hospitals that have available beds.

In determining the availability of beds for the care of casualties, certain major factors must receive primary consideration. These include the number of available surgeons, nurses, physicians, anesthetists, shock teams and x-ray personnel. The number of available operating rooms is a vital consideration. One must give serious thought to Doctor Bachr's admonition not to overcrowd the individual hospital. He places particular stress on the fact that very few hospitals could adequately care for more than 50 casualties in twenty-four hours. The whole question of adequacy of supplies, including stretchers, blankets, splints, plasma and tetanus antitoxin, must receive proper consideration. It is pleasing, indeed, to pay tribute to the hospitals in Massachusetts that have spent substantial sums for adequate preparation to meet

possible demands made on them at the time of the emergency. Supplies have also been provided, and more are to come from state and federal sources.

Facilities for Evacuation

The availability of beds for casualties is dependent on the organization of sound methods for the evacuation of patients. These include: discharge of convalescents to their homes, nursing and convalescent homes, and other designated places, discharge of wounded patients not requiring hospitalization to the places designated above; and evacuation to base hospitals.

In the event of extensive recurrent bombing, as well as of serious damage to emergency hospitals, it will be necessary to evacuate patients extensively to base hospitals.

Elaborate plans have been developed on a statewide level for the establishment of base hospitals. It is planned to use state sanatoriums for tuberculosis, mental hospitals, institutions under the Department of Public Welfare and, possibly, federal hospitals. Plans for supplemental staff organization are in the process of development. The transfer of wounded from local emergency hospitals to base hospitals is the responsibility of the Women's Defense Corps of the Massachusetts Committee on Public Safety. Arrangements for such transfer will be made by the chief medical officer on request of the representative of the emergency hospital. The medical officer will relay this request to the regional medical officer of the district, who will take the necessary steps for the arrangement of such evacuation.

Requests for the evacuation of patients from the emergency hospitals to their homes will be made to the chief medical officer, who will arrange for needed transportation through the American Red Cross.

Regional hospital officers and a state hospital officer have recently been appointed. Among the functions of the latter are studies of existing hospital resources, including base hospitals, methods and routes for prompt transportation from emergency to base hospitals, essential staff and equipment, and needs.

Decontamination

The subject of decontamination of patients suffering from chemical warfare is of serious concern to hospitals. Emergency hospitals are expected to provide facilities for the decontamination of patients, particularly of the type suffering from both gassing and injury. It is recommended that such facilities be built or made a part of the admitting unit of the emergency hospital.

The decontamination unit should ideally provide for three rooms, thus making the following possible: room for removal of contaminated clothing, room for washing and other essential decontamination treatment, and room for clothing of patients and emergency treatment of wounds. For their protection, attendants should wear masks, gas-proof gloves and clothing. It has been strongly emphasized that decontamination of the patient must be carried out before admission to the hospital for treatment.

* * *

In this description of the place of the hospital in civilian defense and the present status of hospital preparedness, it is fitting to call attention to the problems that the war has created for the hospital structure. Staffs have already been materially depleted. The nursing shortage is constantly increasing, and lay employees are frequently preferring the more lucrative opportunities that industry offers. The needs of the Army and Navy, however, must be met, and the war must be won. Many physicians who have retired from hospital staffs are gladly coming back to fill the gaps created by those who have gone into the Service. Nursing aides are rendering invaluable help in replacement of nurses who have enlisted. Volunteers, who deserve unstinting praise, are frequently taking the place of paid personnel.

In sections of the country where the staffs of hospitals are expected to play the double role of providing for medical services in the field and in the hospital,—and here in Massachusetts, where they are so willingly organizing themselves to care for the injured brought to their doors,—there will be much to do in the event of hostile penetration of our shores.

To the glorious heritage of the hospitals of America, which have grown from a modest total of 150 hospitals less than sixty years ago to their present imposing number of over 6500 institutions, is now added the opportunity for service to the civilian population, exposed to the possible hazards of war brought to their own hearthstones. In planning for the efficient functioning of our hospitals in these times of great stress, one may learn much from the bitter experiences of the hospitals in England. Bitter, however, as was their tragic lot, we salute their indomitable will for service, and we glory in their refusal to be conquered. We join with them in this great privilege for service to our neighbors, in this great enterprise with freedom our goal and, God willing, our reward.

330 Brookline Avenue

MEDICAL PROGRESS

DIAGNOSTIC ROENTGENOLOGY: DANGERS ASSOCIATED WITH FLUOROSCOPY*

RICHARD SCHATZKI, M.D.†

BOSTON

IT is likely that the opportunity for x-ray injuries will increase during wartime. In spite of the efforts of the Army and Navy to use specialized, well-trained radiologists, it can be assumed that quite often fluoroscopies of fractures, as well as fluoroscopies in the search of foreign bodies, will have to be performed by men who have had no, or inadequate, training in radiology, and the possibility of injuries exists. Such a danger appears so imminent that this report is devoted exclusively to its discussion.

Every physician remembers, either from his own experience or from the description of others, the extensive injuries produced by x-rays in the first few years after their discovery. At present, x-rays are used so extensively for diagnostic work and injuries seem to have become so rare that it may appear as if x-rays had lost their dangerous qualities. It is true that in many ways modern equipment is safer than that used in the early days of x-ray investigation. The danger of electrical shock no longer exists in modern shock-proof apparatus. Shielding has, in modern types of tubes, eliminated the radiation that formerly escaped from the old glass-bowl type of tube into the examining room outside the field defined by the shutter. But these improvements have not changed the inherent biologic qualities of x-rays. The rays used for the actual examination are still the same that killed a large part of the first generation of radiologists. Owing to technical improvements and particularly to increased knowledge of the inherent qualities of x-rays, the proper application of these rays is no longer dangerous; however, if used excessively and indiscriminately, they obviously will still produce damage. Evidence is accumulating to show that in recent years there has been a disquieting increase rather than a decrease in the number of skin injuries resulting from the use of x-rays.

From 1938 to 1941, Uhlmann¹ saw 70 patients with radiation injuries to the skin. In 40 of these cases, the injuries resulted from the use of x-rays

for diagnostic or technical purposes; only in 30 cases were the injuries caused by x-ray or radium treatment. (Fourteen, or about half, of the latter had been treated for nonmalignant lesions!) There were 27 physicians, 4 dentists and 4 physicists among this group of 70 patients, but only 3 of them were radiologists, and they had been exposed to radiation from twenty to forty years. Of the remaining 32, 28 attributed their injuries to diagnostic work: 4 dentists had been accustomed to hold the films in the patient's mouth during the exposure, 4 physicians had been injured while attempting to remove foreign bodies, and 2 pediatricians had been in the habit of holding babies behind the fluoroscopic screen. Among the non-professional patients, only 6 had been treated by a trained radiologist. In no case was a radiologist responsible for injuries occurring in the course of diagnostic procedures. Uhlmann emphasizes the high percentage of injuries in physicians due to diagnostic work—a fact that he ascribes to a variety of causes, including “unsatisfactory equipment, inefficient protection, inadequate knowledge of the dangers involved, or simple carelessness, since in some instances the injurious effects are unquestionably due to inexcusable disregard of protective measures.”

Leddy and his co-workers,²⁻⁴ in several papers, have stressed the bad effects that result from indiscriminate use of x-rays. From 1919 till 1939, they saw 235 physicians with definite radiodermatitis. Eighty of these physicians were seen within the last six years of this period. The serious character of the radiodermatitis in these physicians is emphasized by the fact that almost 50 per cent of them had either epitheliomas or ulcers due to radiation. In at least 101 cases the damage was attributed to exposure during fluoroscopy. There were only 8 radiologists among the total group, and in only 4 of these was the damage due to fluoroscopy. Leddy and his co-workers found the following main causes of injury: carelessness in the handling of radium and radon—a minor factor; needless exposure of the hands during radiography, for example, in the taking of dental films, the performance of radiopaque injections, the holding of difficult patients and of children, and the holding of cassettes in the preparation of complicated

*From the Department of Radiology, Massachusetts General Hospital.

†Instructor in roentgenology, Harvard Medical School; radiologist, Massachusetts General Hospital.

radiograms; and poorly performed fluoroscopy. As stated above, the last was by far the most important factor. Further investigation showed that none of the physicians in question used lead rubber gloves regularly, and about one third of them used no protective devices whatever. The most dangerous fluoroscopic methods were removal of foreign bodies and reduction of fractures.

Two outstanding facts in Leddy's papers should be emphasized. One is the markedly increasing number of physicians with radiodermatitis whom he had seen in recent years, and the other is the small number of trained radiologists among his patients. Leddy and his co-workers believe that this merits "serious consideration by those who think that roentgen technique is easily acquired and is safe." They add, "The risk involved in the casual use of the roentgenoscope by those without special training cannot be emphasized too strongly, for mechanical equipment cannot be substituted for mental equipment in any branch of roentgenology."

Scheele and Cowie,⁵ who recently reviewed the irradiation protection in 45 hospitals, 32 of which had more than two hundred beds, describe the large amount of radiation to which the technicians in some of the departments were exposed, usually because of their own carelessness. One of them received 35r while holding a single patient—about one hundred and seventy five times the dose that is considered safe as a daily exposure. Exposures during fluoroscopy, however, were found to be the most excessive ones in this survey, and strong measures to reduce this risk were recommended. In contrast to the findings of Leddy and his co-workers, Scheele and Cowie saw skin damage in 12 out of 60 radiologists. The high incidence found in this survey is probably explained by the fact that finer skin changes were included among the 12 physicians, although epitheliomas were seen in some of them.

To these reports of the recent literature, I should like to add two personal experiences that may illustrate the situation. A few years ago I saw a young physician who had been an intern in one of the large hospitals of this country. One day, a patient with a difficult fracture of both bones of the forearm entered the hospital. While trying to reduce this fracture, the doctor used a shockproof portable unit. He had had no particular training in roentgenology and thought the machine was perfectly safe. Because the unit was shockproof, it was possible for him to put the patient's arm close to the tube, and he soon discovered that by so doing his fluoroscopic light was much brighter. Not satisfied with his reduction, he tried again the next morning and fluoroscoped exten-

sively. The results of these two fluoroscopies were bad burns for both the patient and the doctor. When I saw the doctor, he had lost the terminal phalanges of two fingers, and had severe radiation damage of two additional fingers of both hands (see Fig 11 Daland⁶). In other words, extensive burns are still possible from the use of x rays in the examination of a single patient, if the examination is not done with the necessary precaution.

The following event, which happened recently in Boston, demonstrates the degree of ignorance that may be combined with the possession of x ray equipment. A physician called up a salesman of x-ray apparatus, told him that he was dissatisfied with his x ray equipment and wanted some machine that would not burn. A surgeon might just as well ask for a knife that would not cut!

In summary, one may say that (1) x ray injuries still occur, and there is evidence that they are increasing in number in recent years; (2) that a large number of x ray injuries occur during diagnostic examinations—it is even likely that, at present, more injuries occur from such procedures than from the therapeutic application of x-rays, (3) that modern shockproof x ray equipment does not prevent the occurrence of x ray injuries and, although of great advantage to the skilled worker, is, if used unintelligently, in some respects even more hazardous than the old, nonshockproof equipment, because it allows a dangerously close approach of the patient and of the doctor's hands to the x-ray-producing target⁷, (4) that the commonest cause of injuries is the inadequate knowledge of the examining physician, who does not know enough about the technical setup of his equipment and does not realize the dangers that may involve the patient and himself—the second commonest cause is carelessness, and (5) that severe injury to the patient and the physician may occur from a single faulty examination.

How can radiation damage be avoided? Fluoroscopy is the outstanding cause of radiation injury, and is of the greatest consequence in fracture and foreign body work, particularly during wartime. Further discussion is therefore confined to the elimination of fluoroscopic hazards. The safest way of avoiding injury is the complete omission of fluoroscopy. The British Emergency Medical Service⁸ has circulated a memorandum to all medical officers in which it emphasizes the danger of poorly performed fluoroscopies. According to this memorandum, fractures and foreign bodies should be fluoroscoped only in exceptional cases. The advantages of fluoroscopy are, however, too great in many cases for it to be omitted, but it should be performed by a roentgenologist whenever possible. If this is not feasible, the examining

doctor should be instructed and supervised by a roentgenologist, who should also examine the technical equipment. Furthermore, whoever does fluoroscopy should realize that the danger of radiation damage exists, that the amount of danger is in direct proportion to the amount of exposure, and that it can be avoided.

What is the safe dose to which the patient can be exposed? The dose should be smaller than that which will produce an erythema of the skin — less than approximately 300 r for the type of radiation in question. Because of the variation that may occur in the output of any diagnostic x-ray equipment, not more than half this dose can be considered safe. The output of different machines varies, and can be determined only by actual measurement. Measurements at the Massachusetts General Hospital, performed by Mr. Oliver E. Merrill, showed a variation between 14 and 25 r per minute, measured on the tops of different fluoroscopic tables. The distance of the table top from the target of the x-ray tube varied between 34 and 39 cm.; the measurements were made with 80 kilovolts and 4 milliamperes. In other words, with the setup in this department, actual fluoroscopic time from six to ten minutes can be considered safe, the time varying from machine to machine. It is obvious that this dose should not be repeated frequently at short intervals.

Increase in milliamperage increases the amount of radiation correspondingly. Decrease in the target-skin distance increases the amount of radiation by the square of the distance: that is, if the distance between the target and skin is only 20 instead of 40 cm., the amount of radiation will be four times larger. Insufficient realization of this law is one of the common causes of injuries, especially in modern shockproof equipment, which enables one to come close to the target. Actual measurement shows that 462 r per minute are delivered by the tube of a shockproof portable machine if the ionization chamber is in contact with the tube; in other words, the safe dose defined above at this distance would be delivered in twenty seconds.

Which dose can be considered safe for the examining physician? It is obvious that it must be much smaller than the dose safe for the patient, because of the repeated exposures to which the operator is usually submitted. Never, under any circumstances, should the palpating hand or any other unprotected part of the examiner's body be in the direct beam of the x-rays. The importance of this rule cannot be over-emphasized. However, the examiner cannot avoid being exposed to a certain degree of so-called "scattered rays," which are produced secondarily by objects in the direct beam. Every fluoroscopic room shows some scattered radiation,

which can be demonstrated by the use of a portable fluoroscopic screen or by small dental films, and can be measured accurately by the ionization chamber. It is obviously difficult to determine the amount of exposure to scattered radiation that can be considered safe. Answers to inquiries made by investigators in various countries among roentgenologists who for many years had been exposed to scattered radiation vary in the amount of so-called "safe scattering." The majority of the investigators believe that 0.2 r daily exposure of the total body will do no damage. Scattered radiation is quite unimportant when the dangers connected with fluoroscopy of fractures and foreign bodies are considered. If damage is done by these examinations, it is caused by direct irradiation.

The necessary protective measures are as follows:

Equipment. It is assumed that standard modern equipment is available for the examiner. The tube is shielded and probably shockproof. A filter is in the tube, and if actual measurement shows too large an output, another filter should be added.

The fluoroscopic equipment should include a shutter with which the direct beam can be reduced to the actual size needed. The fluoroscopic screen should be rigidly connected with the tube and should be large enough so that it will be difficult or impossible for the direct beam to go beyond the confines of the screen. A lead glass of sufficient thickness should be in front of the screen. The patient should be placed so that there is a safe distance between his skin and the target of the tube. As described above, the intensity of x-rays decreases with the square of the distance. The output of the x-ray machine varies with the amount of milliamperage and voltage. If 6 milliamperes are used, the output will be one and a half times as much as that with 4 milliamperes. Increase in the kilovoltage from 80 to 90 will double the actual exposure on the patient's skin. The sides of the machine should be constructed so as to emit as little scattered radiation as possible. A primary cone, which is a cone attached to the x-ray tube, is of particular advantage for this purpose. This cone should come as close as possible to the top of the table on which the patient is examined.

Fluoroscopic Technic. Fluoroscopy is an art. The greater the care with which it is performed, the better the results and the less the danger for patient and examining physician. Fluoroscopy should be performed in a completely darkened room. The examiner should not be disturbed by any outside light entering the room at any time. A red light should be connected with the foot switch

so that it will turn on automatically when the current of the machine is interrupted. The examiner should adapt himself with dark glasses, or by sitting in a darkened room, for at least fifteen minutes. To overcome poor visual adaptation by an increase in the tube current is a poor policy. Such a procedure does not compensate for the loss of diagnostic acumen and represents an inexcusable increase of the fluoroscopic risk. An excellent description of physiology and practice of adaptation is given in a recent article by Chamberlain.⁹ Simple ways for testing the optimal degree of adaptation are outlined. In the same article, Chamberlain prophesies the application of the principles of television and ultramicroscopy for fluoroscopy. By amplification, unheard of brilliancy of the fluoroscopic light would result, which would minimize the risk of fluoroscopy and revolutionize roentgenology.

The actual fluoroscopic exposures should be as short as possible. The current should be shut off when it is not actually needed for observation—for example, during discussions or demonstrations. A shutter should be used to define the fluoroscopic field. Keeping the shutter opening as small as possible has a threefold advantage: it improves the fluoroscopic image and decreases the danger to the patient and to the doctor.

Since any handling of a fracture during fluoroscopy markedly increases the risk of the examination, fluoroscopy should be used only to check an obtained position. As emphasized above, the hand of the examiner should never appear in the direct beam of the x-rays. He should wear lead rubber gloves and a lead rubber apron.

Measurement. The actual amount of x-rays to which patient and doctor are exposed should be measured by an ionization chamber. Wherever this is not possible, and I can think of many places where it will not be, particularly under war conditions, the machinery should be carefully checked as outlined above, if possible by a physicist or a roentgenologist, for protection against overdosage and correct definition of the direct beam. The scattered radiation can be fairly easily demonstrated with the help of dental films, which are placed at various exposed areas or, simpler still, with the aid of a portable fluoroscopic screen. A small amount of fluorescence will be present in any fluoroscopic room, owing to the scattering. A leak in the protection, however, can be readily discovered by the

locally increased intensity of light seen on the portable screen, and the leak can be obliterated.

Personnel. The attitude and training of the examiner are the most essential factors in the protective scheme. A well-trained, conscientious examiner can use obsolete equipment safely, whereas an ignorant or careless worker can do irreparable damage with the most modern equipment. An adequate fluoroscopic technique can be learned only through personal teaching. Good descriptions of fluoroscopic technique¹⁰ are helpful but they are not substitutes for such personal training.

Physical data regarding protection, more extensive than those presented in this review, can be found in a number of recent publications.¹¹⁻¹³

* * *

Modern x-ray equipment does not prevent x-ray injuries. In some respects, it is even likelier than old-fashioned machines to produce damage, if used without the necessary knowledge. There is evidence that in recent years there is an actual increase in the number of persons injured by diagnostic procedures. The physician who "does a little x-ray work" is in greater danger than the expert roentgenologist, and it is he who needs protection.² Whoever uses x-ray equipment, particularly for fluoroscopic purposes, should realize the danger to which he exposes the patient and himself, and he should be certain that all possible points of danger have been eliminated, otherwise, serious damage may result.

IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28271

PRESENTATION OF CASE

A sixty-year-old unemployed carpenter was admitted to the hospital because of cough of five months' duration.

Two years before entry, the patient fell, striking his lower right chest against a stake. A roentgenogram was said to show questionable fracture of the eighth rib near the spine. After this, the patient began to have periodic pain in the region of the right nipple, occasionally radiating through to the back, to the right side of the neck and occipital region, or to the right axilla and right upper arm. These attacks occurred once or twice a week, and frequently accompanied damp weather or the lifting of heavy objects. The pain was sharp and intermittent. The patient was otherwise well and was able to continue his work. Eight months before entry, there was some loss of appetite. Five months before entry, there was gradual appearance of cough productive of two or three tablespoonfuls of white sputum. The attacks of pain were aggravated by the cough. After a few weeks, the patient began to feel nauseated. Attempts at vomiting increased the cough. The sputum became foul, leading the patient to consult a physician. A roentgenogram of the chest was said to show "clouding of the right lung." The patient was given *green liquid medicine* and white pills. He remained in bed for about a month, with some resultant improvement in his general condition, and then returned to work. The sputum became increasingly foul and turned green. Two and a half months before entry, the sputum became pink, up to half a pint a day being raised. Gradually, the sputum became frankly bloody. Two months before entry, the patient was forced to stop work because of shortness of breath. There was a weight loss of 10 or 15 pounds in the course of the illness.

The past and family histories were irrelevant. Venereal disease was denied.

On admission, examination showed a poorly nourished, chronically ill man of middle age, coughing and orthopneic. The veins over the neck and arms were prominent, more so on the left than on the right. The heart was of normal size, with a rough systolic murmur at the aortic

area, poorly transmitted to the neck. Coarse rales were heard throughout the right chest, with occasional loud expiratory squeaks and groans over the right upper lung field. There was dullness over an area corresponding to the right upper lobe anteriorly, posteriorly and in the axilla. Breath sounds and vocal and tactile fremitus, however, were not altered in this area. A few small cervical lymph nodes and a solitary left supraclavicular node were palpable but not tender. The liver edge lay just below the costal margin. The abdomen was otherwise normal. There was early clubbing of the fingers. Neurologic examination was negative.

The blood pressure was 110 systolic, 55 diastolic, in the right arm and 105 systolic, 60 diastolic, in the left arm. The temperature was 99°F., the pulse 130, and the respirations 25.

Examination of the blood showed a red-cell count of 4,500,000 with 13 gm. hemoglobin, and a white-cell count of 16,000 with 84 per cent polymorphonuclears. The blood Hinton reaction was positive. The urine was normal. Culture of the sputum showed no beta hemolytic streptococci.

A roentgenogram of the chest showed a huge irregular cavity occupying a completely consolidated right upper lobe. The cavity was about 6 cm. in diameter, and there were multiple nodular projections along its margins. There was only a small quantity of fluid. The arch of the aorta was dilated and prominent, with a suggestion of calcification. The heart was of normal size and shape. The ascending aorta was questionably prominent. There was no definite evidence of bone destruction in the ribs or vertebrae.

The patient continued to drain large amounts of foul-smelling sputum. He was given sulfadiazine. The temperature fluctuated irregularly between 98 and 105°F. On the eighth hospital day, coarse rhonchi were audible throughout both lung fields. The patient became increasingly weaker, and cyanosis appeared. He was given gomenol, with good relief from the foul odor of the sputum. Death occurred later in the day, apparently from respiratory failure.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD D. CHURCHILL: We know that breath sounds are widely transmitted throughout the chest. I examined a man yesterday whose entire right lung had been removed three years previously; in the right axilla, there were normal breath sounds, tactile fremitus and vocal resonance. He had a thoracoplasty, but the transmission of the sounds from the left lung suggested a normal right lung in the axillary region. Pulmonary resection is giving us a new concept about

transmission of sounds into the area over which one is listening with a stethoscope. The x-ray film in the case under discussion makes it obvious that the underlying lung could not produce normal breath sounds. They must have been coming through from adjacent segments of lung.

"There was early clubbing of the fingers." I do not like the term "early." It implies that in a

vocabulary for the subtle odors so useful in clinical medicine.

The x-ray film is quite important. There is a huge irregular cavity within a homogeneously dense right upper lobe (Fig. 1). The X-ray Department are overstepping when they refer to a "consolidated" right upper lobe if they imply consolidation in the pathologic sense. The cavity is

FIGURE 1.

few months it will increase. We have no evidence for that. Some diseases give slight clubbing, others extreme clubbing, and others no clubbing of the fingers. The term "early" means slight or moderate.

I often wish we had a more ample terminology to describe the odor of the sputum because so often the diagnosis can be made by this means alone. Varying odors of the sputum are like the bouquets of vintage wines. The word "foul" does not mean anything and, in addition, always startles the patient. It may be more informative to ask if the sputum has a bad taste. The patient will tell you that his sputum tastes bad, but if you ask if it is "foul," he will say no. It is unfortunate that we are lacking a precise descriptive

6 cm. in diameter. There are multiple nodular projections along its margins.

Will you comment on the x-ray film, Dr. Schatzki? Do you care to make a more clearly definitive statement regarding calcification and prominence of the ascending aorta?

DR. RICHARD SCHATZKI: There is definite calcification in the arch of the aorta. I should say that the ascending aorta is dilated, and also the arch. The descending is normal in size so far as I can see on the film.

DR. CHURCHILL: Is the heart of normal size?

DR. SCHATZKI: Yes.

DR. CHURCHILL: Is there anything to add to the description of the cavity?

DR. SCHATZKI: I think it is a fairly good description. You are right in considering the term "consolidation" a poor one. It is very often erroneously used in the sense of density, as you know.

DR. CHURCHILL: Let us take up the question of cardiovascular disease. There was a positive blood Hinton reaction, a dilated aorta, with calcification in its walls, a rough systolic murmur over the aortic area and a blood pressure of 110 systolic, 55 diastolic.

Dr. Breed, do you want to pick that up from the medical standpoint and tell us what was wrong with the cardiovascular system?

DR. WILLIAM B. BREED: I do not believe that the variation of blood pressure between the right and left arms was more than normal. The mere recording of such figures tends to call more attention to the variation than is justified. The pulse pressure of 50 to 55 without an aortic diastolic murmur is not particularly significant, and in the x-ray picture the possibility of syphilitic aortitis is not so likely as an arteriosclerotic aorta in a man of sixty. However, I should like to question Dr. Schatzki a little more specifically on that point—can one differentiate by this x-ray film a syphilitic from an arteriosclerotic process?

DR. SCHATZKI: You mean so far as tortuosity and dilatation of the aorta are concerned. In a large number of cases of syphilitic aortitis, we call the aorta normal, knowing that we cannot see significant pathologic changes in many of them. We usually make an understatement rather than an overstatement in that respect—it is better not to call the aorta dilated than the other way around. But when we say dilatation, I think it is quite dilated, and this particular aorta was dilated in that sense. There is not such a degree of dilatation in arteriosclerosis unless there is a dissecting arteriosclerotic aneurysm.

DR. BREED: You never speak of a tortuous aorta as dilated?

DR. SCHATZKI: We should not per se. I think that is a definite mistake.

DR. CHURCHILL: Do you say that this was syphilitic aortitis?

DR. TRACY B. MALLORY: How about the calcification?

DR. SCHATZKI: I should say that syphilitic aortitis with dilatation shows calcification in a very large percentage of cases. As a matter of fact, the presence of calcification rather proves than disproves the diagnosis, particularly if the calcification is in the ascending aorta.

DR. CHURCHILL: Do you agree with that, Dr. Mallory?

DR. MALLORY: I agree with Dr. Schatzki that calcification in the thoracic aorta is unusual in the arteriosclerotic aorta except in advanced cases; in the abdominal aorta, it is a different proposition.

DR. SCHATZKI: I cannot see calcification in the ascending aorta. We often see calcification in the arch of an arteriosclerotic aorta, just where we see it in this particular case. If it were in the ascending aorta, it would be more in favor of syphilis.

DR. MALLORY: I should have qualified my statement. Calcification is common in the arch. A favorite spot is the dimple of the ductus arteriosus. In the ascending and frankly descending portions, I do not believe we often see it.

DR. SCHATZKI: We do in very advanced cases.

DR. CHURCHILL: Dr. Breed, you are still my medical consultant. What do you call this?

DR. SCHATZKI: If the patient had no definite evidence of regurgitation, I do not see how we can decide the question. Is that right?

DR. BREED: Yes; he had no diastolic murmur. This does not rule out syphilitic aortitis, but it is evidence against it.

DR. SCHATZKI: The fact that the heart shadow was normal probably rules out aortic regurgitation.

DR. BREED: Yes, probably.

DR. FULLER ALBRIGHT: Was the aortic second sound recorded?

DR. MALLORY: There is no note on that.

DR. CHURCHILL: Then you interpret this, Dr. Breed, as syphilitic aortitis?

DR. BREED: I shall take the arteriosclerotic side, for the sake of argument.

DR. SCHATZKI: I shall take the syphilitic side.

DR. CHURCHILL: We know that the patient had a pulmonary abscess, with a fluid level in a cavity and foul sputum. The only question is, Was this abscess in the center of a cancer, or was it not? We have no direct evidence for cancer other than the x-ray film and the course of the patient, which, however, is perfectly consistent with a noncancerous lung abscess. The history and physical examination do not point either way. The question whether or not this was an abscess within a cancer comes down solely, it seems to me, to interpretation of the film. I maintain that the thickened wall, with the nodule extending into the cavity, indicates that it was a necrotic tumor—a primary cancer. I can come to no other diagnosis. That is an x-ray diagnosis, and I should like to check it with Dr. Schatzki.

DR. SCHATZKI: You must remember the cases in which we used the same reasoning and were wrong! In those cases, a markedly irregular out-

line of the inside of the cavity turned out to be caused by debris in an abscess.

Dr. CHURCHILL: I do. The debris abscess gives a thumbnail appearance, rather than the picture presented by this case.

Dr. SCHATZKI: I agree; and from this film I should not hesitate to call it cancer.

Dr. CHURCHILL: I can reach no other conclusion on the evidence. The clinical course could go with either. So that, purely on the x-ray visualization of the lesion, I say lung abscess within a primary cancer of the lung.

Dr. CHURCHILL: I can mention it.

Dr. COPE: And would you exclude it?

Dr. CHURCHILL: Not definitely. I can mention it as one of the things that turn up now and then when we are wrong. It is like the safeguard of the medical student who always puts syphilis down at the end of a list to include everything in his differential diagnosis; it might be syphilis.

CLINICAL DIAGNOSES

Carcinoma of lung, with secondary abscess.

Syphilitic aortic aneurysm.

FIGURE 2

Dr. MALLORY: Do you accept Dr. Breed's or Dr. Schatzki's opinion regarding the aorta?

Dr. CHURCHILL: I have no competence to decide between them. I shall let the two gentlemen argue it out.

Dr. BREED: Dr. Albright suggests that if this was cancer in the right upper lobe, it may have pushed the aorta over to make it appear larger than it was. I think that is a good point.

Dr. SCHATZKI: I think we can differentiate between tortuous aorta and dilated aorta if it is markedly dilated.

Dr. MALLORY: Would anyone care to defend a primary aneurysm occluding a bronchus by external pressure and secondary abscess of the lung?

Dr. CHURCHILL: I am not willing to accept this as aneurysmal phthisis.

Dr. OLIVER COPE: Would Dr. Churchill mention gumma with abscess?

Dr. CHURCHILL'S DIAGNOSES

Carcinoma of lung, with secondary abscess.

Cardiovascular disease involving aorta, nature undetermined by medical and radiologic consultants.

ANATOMICAL DIAGNOSES

Carcinoma of upper-lobe bronchus of right lung, with secondary abscess.

Metastasis to regional lymph nodes and left adrenal gland.

Syphilitic aortitis with aneurysm.

Bronchopneumonia, terminal.

Urolithiasis medicamentosa (sulfadiazine).

PATHOLOGICAL DISCUSSION

Dr. MALLORY: Autopsy showed a mediastinum filled with a large aneurysm, syphilitic in origin. It replaced the arch, half the ascending and al-

most two thirds of the descending aorta, stopping sharply at a point about 4 cm. above the diaphragm. Figure 2 shows the thoracic organs viewed from behind. The dilated descending aorta has been reflected over the left lung. The cavity in the right upper lobe appears black, and a white tumor nodule is visible in the bronchus to the upper lobe. Smaller tumor masses surround the cavity. The syphilitic aneurysm was apparently coincidental and had nothing to do with the symptoms.

DR. BREED: Then it is merely an academic discussion of x-ray diagnosis. The disease had nothing whatever to do with the patient's health or death.

DR. MALLORY: So far as this cardiovascular syphilis is concerned?

DR. BREED: Yes.

DR. MALLORY: That is true.

There were metastases to the adrenal glands. These were the only distant metastases found.

DR. CHURCHILL: Was it an epidermoid carcinoma?

DR. MALLORY: It was so undifferentiated that we did not classify it.

DR. SCHATZKI: Where did the dilatation start?

DR. MALLORY: It began shortly above the valve, 1.5 cm. to be exact, but was only slight, measuring 8 cm. in circumference up to the arch; then it widened to 10 and 14 cm. farther on.

CASE 28272

PRESENTATION OF CASE

A thirty-nine-year-old housewife entered the dental clinic of the hospital complaining of a growth of tissue on her gum.

The patient had always been negligent of her teeth, occasionally pulled the loose ones herself, and eighteen years before admission had had fifteen teeth extracted. Seven years before admission, she noticed in the left upper jaw a painless growth of tissue that occasionally bled and gradually increased in size, but had remained the same for the previous three years. She had had no dental care in seven years. Examination showed a large mass of hypertrophied tissue about 3 cm. in diameter overlying the maxilla in the left cuspid area. It was firm, attached by a very hard pedicle, and had a fissure running through it in the antero-posterior direction. A tentative diagnosis of epulis was made, and the patient was referred to the medical service for blood calcium and phosphorus studies.

On the medical service, it was learned that four years before admission the patient slipped and fell,

fracturing her scapula and right patella. While in bed, she gained about 70 pounds in weight. The bones healed readily, although the patella remained displaced. Two years before entry, the patient was sick for one month with low-back pain, fever and chills unaccompanied by frequency, dysuria, hematuria or changes in the appearance of her urine. Eight months before entry, she noticed in the left neck a constant soreness, which radiated to the head and seemed worse immediately before the menstrual periods; she attributed this pain to the growth in her mouth. Dizziness and vomiting without nausea appeared five weeks before entry. The vomitus was green and watery, had no relation to meals, and occurred approximately every other morning. These symptoms were accompanied by a great thirst and craving for sour fluids. In general, the appetite was small, and the patient rarely ate sweets, milk, bread or cheese.

The patient had had the usual childhood diseases and, thirteen years before admission, a cholecystectomy and appendectomy. Her father had died at fifty of hemophilia, and her mother at fifty of diabetes. One sibling died at twenty-five of tuberculosis. She stated that her sister's children and her own two offspring might have hemophilia.

On examination, the patient was well developed and extremely obese, but appeared well. The skin was clear and of fine texture, and there was a large scar in the left breast. On the dorsum of the third left metacarpal bone was a hard tumor measuring 3 by 5 cm. There were marked pyorrhea and caries of the remaining teeth, and in the maxillary left cuspid area there was the lesion observed in the dental clinic. Examination of the heart, lungs and abdomen was negative. The right patella was displaced upward above the knee joint. Examination of the fundi and nervous system was negative.

The blood pressure was 140 systolic, 95 diastolic. The temperature was 98 to 100°F., the pulse 90, and the respirations 20.

Examination of the urine showed a +++ test for albumin, an occasional hyaline cast, and a +++ Sulkowitch test for urinary calcium. A urinary-concentration test was normal, and a phenolsulfonephthalein test yielded 18 per cent of the dye in fifteen minutes and another 10 per cent in thirty minutes. Examination of the blood showed a red-cell count of 4,190,000 with a hemoglobin of 82 per cent, and a white-cell count of 7500 with 54 per cent polymorphonuclears. The serum calcium ranged from 13.8 to 16.6 mg. per 100 cc., the phosphorus from 0.92 to 2.3 mg. per 100 cc., and the phosphatase from 3.3 to 9.7 Bodansky units. The nonprotein nitrogen of the blood serum was 17 mg. and the proteins 6.8 gm. per 100 cc. A blood

Hinton reaction was negative. The stools were guaiac negative.

X-ray films of the teeth showed absent lamina dura, with marked alveolar absorption about many, and severe caries. There was a cyst involving the alveolar process of the left upper jaw in the incisor, cuspid and bicuspid areas. The bones of the vault had a mottled appearance because of multiple small areas of rarefaction. The bones of the skeleton were decalcified. There was a large cyst involving the proximal phalanx of the left middle finger, another involving and expanding the third right metacarpal and a smaller cyst in the first right metacarpal; a fourth was present in the carpal scaphoid on the left. There was an old fracture of the left patella, with dehiscence of the fragments, and a supranumerous high epicondyle in the left humerus. X-ray films of the chest showed enlargement of the heart in the region of the left ventricle and a tortuous aorta. No pathologic mass was seen in the upper mediastinum. The diaphragm was slightly high, but there was no evidence of intrapulmonary disease. The esophagus was demonstrated by barium and was normal.

An electrocardiographic recording showed a normal rhythm, a rate of 84 and a PR interval of 0.15 second. There was slight left axis deviation, sagging ST interval in Leads 1 and 2, slight inversion of T₃ and biphasic T₄.

One month after admission, an exploration of the neck for parathyroid tumor was performed. Both upper parathyroid glands were identified and appeared normal. No others were found.

DIFFERENTIAL DIAGNOSIS

DR JACOB LERMAN: I should like to comment on several points in the history and physical examination. The presenting symptom was that of a painless lesion of the left upper jaw, slowly growing and obviously not very malignant. The next significant feature was the story of fractures resulting from slight trauma. This immediately suggests pathologic fractures; good healing is consistent with some types of pathologic fractures. The gain of 70 pounds in weight does not seem to be significant; the low back pain, fever and chills are difficult to explain. The evidence is against urinary infection. The soreness in the left neck is also difficult to explain. If it was due to a lesion similar to the one in the jaw, the exacerbation before menstrual flow is understandable. The change in electrolyte balance that occurred premenstrually may have increased the volume of an encapsulated or enclosed mass so as to produce increased pressure. The dizziness and vomiting appeared to be nonspecific in origin. The abdominal operation raises the possibility of adhesions as a cause for

vomiting. However, the absence of pain is against this. The thirst and craving for fluids may have been caused by vomiting, by excessive excretion of sugar or electrolytes, or by symptoms of diabetes insipidus. The low intake of milk and cheese is significant.

Physical examination gives us the information of a tumor of the left hand, in addition to the one in the jaw. I cannot tell whether this tumor was part of the bone or merely adherent to it.

The important laboratory data consist of a high blood calcium, low blood phosphorus, +++ Sulzowitch test and normal to slight elevation of phosphatase. There was evidence of slight renal impairment—namely, a +++ test for albumin and occasional hyaline casts. The tests for renal function were negative. The serum protein was normal. The significant findings by x-ray were the absent lamina dura, cysts in the jaw and hand, areas of rarefaction in the vault, decalcified skeleton and old fracture of patella. The electrocardiographic changes, in the absence of digitalis, suggest coronary disease in the menopause. I cannot see why hypercalcemia should produce these electrocardiographic changes. One would rather expect changes in conduction as a result of high blood calcium.

The most logical diagnosis is primary hyperparathyroidism. The evidence for this consists in the probable pathologic fractures, dizziness, vomiting, thirst, bone cysts, bone decalcification in the presence of a low calcium intake, changes in the teeth by x-ray, hypercalcemia, low blood phosphorus and hypercalciuria. The slight renal damage is of the type seen in this disease. The relatively low phosphatase is somewhat unusual.

Several other conditions must be considered. One is secondary hyperparathyroidism; there was not enough renal damage to cause retention of phosphorus. Metastatic bone lesions, lymphoma involving bones and sarcoid are others. Any of these conditions may give a high calcium in the blood and urine, but the phosphorus is either normal or elevated. The duration of the condition and appearance of the skull in the case under discussion are against malignant lesions. Multiple myeloma is suggested by the skull plates, high blood calcium, albuminuria, low blood phosphorus, absence of Bence-Jones proteins in the urine, normal serum protein and bone cysts. If renal damage is produced by multiple myeloma, one may get the secondary type of hyperparathyroidism. Rapid mobilization of calcium results from immobilizing the greater portion of the skeleton, the blood stream being flooded with calcium and phosphorus; there is nothing to suggest the situation in this case.

Dr. Albright and I have followed 2 patients in this hospital and Dr. John Howard has followed 1 at Johns Hopkins Hospital with the following characteristics: high blood calcium and phosphorus, high urinary calcium, advanced renal damage, elevated serum protein, no Bence-Jones protein and negative sternal biopsies. The only common finding in all these cases was a history of excessive intake of calcium and alkali. This patient does not belong to this group because the renal damage was not extensive, the serum protein was normal, the phosphorus was low and the intake of calcium was low.

In conclusion, I must say that hyperparathyroidism, due either to generalized hyperplasia of all the parathyroids or to an adenoma of one parathyroid, is the most probable diagnosis. Since the surgeon did not confirm this, there are certain possible explanations. The surgeon may have been mistaken about the character of the parathyroid glands, and the pathologist may have discovered either hyperplasia or a small adenoma. The patient may have died, and the pathologist may have discovered the true nature of the disease. Knowing the perseverance of the surgeons, I suspect that a second search was made, and, as often happens, a parathyroid adenoma was found elsewhere.

CLINICAL DIAGNOSES

Hyperparathyroidism.

Parathyroid adenoma of mediastinum.

DR. LERMAN'S DIAGNOSES

Hyperparathyroidism.

Parathyroid adenoma of mediastinum.

ANATOMICAL DIAGNOSES

Hyperparathyroidism.

Parathyroid adenoma of mediastinum.

PATHOLOGICAL DISCUSSION

DR. OLIVER COPE: Dr. Lerman's surmise is correct; a second operation was performed in search of a parathyroid tumor. I have brought along a colored motion picture to show you as proof. Such pictures are expensive to make, and I should not have had this one taken of the operation if we had not been reasonably sure of the diagnosis of hyperparathyroidism.

It is fair to say that Dr. Lerman was not given all the evidence that is now available, or should be available, to the surgeon trained in the care of this disease. The two parathyroid glands disclosed at the first operation in the neck were not normal. They were atrophic, and should have been termed "uninvolved." In the presence of an adenoma, the uninvolved glands are not called on to function and undergo an atrophy of disuse. This

atrophy apparently affects only the epithelial cells, and the proportion of fat therefore rises and the color changes more to that of normal fat. It is only recently that I have been able to recognize this difference in gross appearance between the normal and uninvolved glands. This has come only by comparing the normal glands seen in patients with thyroid disease and those of patients explored in search of a parathyroid tumor who turn out not to have one with the uninvolved glands seen in patients proved to have hyperparathyroidism due to an adenoma. Microscopically, this atrophy is difficult to identify, since normally there is a considerable variation in the proportion of fat to epithelial cells; in gross at the operating table, however, the finding of a small, yellower than normal parathyroid gland does suggest the presence of an adenoma in one of the other parathyroid glands.

Having searched the neck and the posterior mediastinum at the first stage in this patient, I left the operation reasonably sure that a tumor existed in the anterior mediastinum. The presence of an adenoma had been excluded in all other possible positions in which parathyroid glands can occur. The anterior mediastinum, alone, remained. The motion picture is therefore of the exploration of the anterior mediastinum. The first step in the exploration is to expose the anterior surface of the sternum. An opening is made along the sternum in the right third interspace by insertion of a finger. The pleura is depressed and then pushed laterally. Another finger is inserted above in the manubrial notch. These are brought together beneath the sternum, and a free passage is made for the sternal knife. The pleura and pericardium are then carefully separated further by blunt dissection as the two portions of the sternum are retracted laterally. The anterior fascia within the anterior mediastinum is then opened into. At this point, we spied an adenoma lying anterior to the ascending aorta, slightly on the right side. One can see, on the far side of the incision, the pleura of the left side. The adenoma now appears in the center. It is quite a large flat tumor, and at its upper pole there are no blood vessels. As the tumor is lifted into the field, the entire vascular pedicle is at its lower pole. The arterial branches come from the mediastinal vessels feeding the upper pericardium. The position of the vascular tree is an important point. Several articles in the literature suggest that if a parathyroid adenoma exists in the mediastinum, a vascular pedicle will be found leading from the thyroid gland down into the chest. This may be true if the parathyroid gland, at the end of embryologic development, resides somewhere near the thyroid and is displaced into the mediastinum later, when it is enlarged by

the adenoma. Such displacement occurs partly by the motion of the larynx and thyroid region with swallowing, and partly by the negative intrathoracic pressure. But in this patient we believe that the parathyroid tissue arrived in the anterior mediastinum during its embryologic development. It came down with the thymus from the upper or third branchial cleft, and it derived its blood supply from the neighborhood in which it finally resided. When the adenoma developed in this gland, the blood supply, of course, remained the same. The absence of a vascular pedicle from the neck to the mediastinum therefore does not exclude the presence of a parathyroid gland in the chest. It is conceivable that one could have reached the tumor in this case from the neck incision by inserting the fingers down behind the sternum and catching it. In view of the size of the arterial blood supply, any attempt to deliver the tumor from the mediastinum into the neck would have been risky. Undoubtedly, the vascular pedicle would have torn, and there would have been an intrathoracic hemorrhage, which could not have been controlled from the neck. We have delivered three such tumors from the mediastinum into the neck, but we now know it to be risky, not only because of hemorrhage but also because of possible pneumothorax. Moreover, it is not possible to reach far enough down with the fingers inserted in the neck. One patient who came to autopsy had a parathyroid adenoma resting on the right auricle on the upper folds of the pericardium. This was at least 5 cm. below the reach of fingers inserted into the notch of the manubrium. Therefore, the operation of exploration for a parathyroid tumor is now divided into two stages. In the first stage, the neck and posterosuperior mediastinum are explored — that is, the region that can be exposed to direct vision. If the adenoma is not found in this exploration, it

must be in the anterior mediastinum. At the second stage, the sternum is split so that the anterior mediastinum can be explored under direct vision.

DR. TRACY B. MALLORY: I have only to add that the tumor was a characteristic parathyroid adenoma on microscopic section — a large one, with many glandular and cystic spaces in it.

DR. JOSEPH C. AUB: Did you look for the fourth gland?

DR. COPE: We did not. The size of this adenoma was adequate to account for the severity of the disease that this patient had. If we had found a small adenoma, we certainly would have looked for the fourth gland to make sure that it did not contain a second adenoma. About 10 per cent of our patients with adenomas have had two adenomas. The weight of adenomatous tissue is roughly proportionate to the degree of elevation of the blood calcium. This patient's tumor was a large one. The chances were against her having a second adenoma. Actually, I did look throughout the thymus gland, which was the most likely place to find the fourth, but did not encounter it. The subsequent course of the patient has shown that there is presumably no further hyperactive tissue.

A PHYSICIAN: What percentage of glands are found in the mediastinum?

DR. COPE: Of the 67 cases of proved hyperparathyroidism at this hospital, 60 were due to adenoma and 7 to hyperplasia. Of the cases with adenoma, 13 adenomas were found in the anterior mediastinum, and 5 in the posterior mediastinum. This gives an exaggerated percentage, since cases sent to this hospital for secondary explorations have turned out in large proportion to have the adenoma within the mediastinum. I believe about 10 per cent would be the true figure.

WAR AND MASSACHUSETTS PHYSICIANS

THIS issue of the *Journal* contains a series of six papers presented at the annual meeting of the Massachusetts Medical Society that discuss the war effort as it relates to various aspects of medicine. The medical profession of any nation plays such a significant role in modern warfare—in combat areas, in training centers, in industry and in civilian communities—that each article should be carefully read by all physicians, particularly those who practice in Massachusetts, and even including those who listened to the papers at the annual meeting.

Dr. Frank H. Lahey forcefully emphasizes the need for young physicians in the armed forces,

states that *all* physicians will eventually be utilized in one capacity or another if the war continues, and exhorts those who are classified as "available" to apply immediately for commissions.

Dr. Reginald Fitz discusses the problems and experience of the Massachusetts committee of the Procurement and Assignment Service. He, too, stresses the need for young physicians and presents an analysis of the status of the 3000 Massachusetts physicians under forty-two years of age. According to his figures, 1200 of these young physicians are necessary to the health and welfare of civilians, whereas the remaining 1800 comprise a pool in which the essentiality or availability of each individual must be determined.

Dr. Elliott C. Cutler outlines the organization and modus operandi of the Medical Division of the Massachusetts Committee on Public Safety, pays due tribute to the time and effort given by Massachusetts physicians to the establishment of local medical committees, to the training of mobile medical units, to the proper equipping of hospitals and to provisions for medical and civilian evacuation, and asks that this interest be continued.

Dr. A. William Reggio covers the physician's role in first aid, particularly emphasizing the need for all physicians to become thoroughly familiar with accepted first-aid procedures, so that they may be qualified to give first-aid courses, to instruct intelligently the members of first-aid parties and the helpers of the medical first-aid posts and to apply first-aid measures themselves, if necessary.

Dr. Bennett F. Avery presents the problems that have been raised by the accelerated schedule of education adopted by nearly 90 per cent of the medical schools in this country and by the need for more detailed instruction in matters pertaining to military medicine.

Finally, Dr. Charles F. Wilinsky gives certain objectives that may be considered the minimum goal of all hospitals during the emergency. These include the protection of physical property, the care of casualties and facilities for evacuation.

All these matters are of vital interest to Mas-

sachusetts physicians, and by the publication of these six papers in a single issue of the *Journal* it is hoped that a means will be furnished whereby each physician will become thoroughly familiar with his responsibilities during the present crisis

THE SINISTER SHEPHERD

PROFESSOR SIMUEL E MORISON* in his *Admiral of The Ocean Sea* has analyzed the available data and opinions regarding the possible transmission of syphilis from the New to the Old World as the result of the discovery of America by Columbus. One chapter, entitled "The Sinister Shepherd," is an excellent summary of all that is known of importance about this controversial subject. He should receive wide recognition from physicians for his handling of the perplexing problem, since he, a nonmedical historian, has done a better job than any medical writer on the topic.

As Professor Morison points out, the evidence appears to be sound that syphilis existed in America before the first voyage of Columbus in 1492. It was present, in all probability, among the Indians of the islands and continent. He reached this conclusion only after careful deliberation, and in spite of the fact that some historians and archeologists do not agree.

The question whether syphilis existed in Europe before Columbus returned in 1493 is a much more difficult one to answer. Everyone knows that, in 1495 or 1496, syphilis became rampant in Europe. Before 1495, however, there is no clear clinical description of a case that one can say with certainty was syphilitic. On the other hand, Sudhoff collected a great amount of evidence to prove that syphilis existed in France, Germany and Italy long before 1493. According to this eminent historian, the march of the French army on Naples in 1495 simply stirred up and spread the organism, which was already in existence. Other historians believe that Sudhoff is wrong about this matter, for he based his arguments on

uncertain data and a few clinical descriptions that may point to another disease. It seems certain, moreover, that syphilis, in the form and to the extent in which it ravaged Europe in 1495 and after, could not have been evident before that date. If syphilis had been present before that time, it must have been in a dormant form and something must have served as an activator. Was this activator the syphilis brought over by the sailors with Columbus?

Professor Morison does not believe that the sailors were actually responsible for bringing over the syphilis, but he does think that the Indian captives whom Columbus brought back on his first voyage were probably carrying the *Treponema pallidum*. None of the crew were ill, even when they reached Spain. If they had acquired syphilis before leaving the New World, they would surely have shown evidence of the disease at that time, particularly in view of the virulent type of syphilis that subsequently developed. The Indian captives, on the other hand, might have carried the disease without manifesting marked signs while on the voyage, only to transmit it to European soil where, because no one was protected against this type of syphilis, a virulent outbreak occurred. This is the basis of Professor Morison's argument, and he has presented so strong a case that it will be accepted by many. This hypothesis, moreover, is supported by three reputable writers of the middle sixteenth century—Las Casas, Oviedo and Diaz de Isla, the last a house physician in a Lisbon hospital. It seems, therefore, that America was the original home of the "sinister shepherd."

MEDICAL EPONYM

PLAUT-VINCENT'S ANGINA

Hugo Carl Plaut (1858-1928) of Leipzig published his "Studien zur bakteriellen Diagnostik der Diphtherie und der Anginen [Studies in the Bacterial Diagnosis of Diphtheria and the Anginas]" in the *Deutsche medizinische Wochenschrift* (20:920-923, 1894). A portion of the translation follows:

Five successive cases of simple angina deserve mention because of the type of micro-organism that, there seems to be no doubt, was their cause. Inspec

*Morison, S. E. *Admiral of the Ocean Sea. A Life of Christopher Columbus*. 2 vol. 893 pp. Boston: Little Brown and Company, 1942.

tion of the oral cavity, which contained many carious teeth, showed a dirty exudate on both medial surfaces of the markedly swollen tonsils and the left side of the uvula. . . . Microscopic examination of the exudate showed it to consist bacteriologically of nothing but Miller's spirochetes and Miller's bacilli. . . . Miller's bacilli are . . . much larger than the diphtheria bacilli, are, in contradistinction to these, pointed at the ends, and are always associated with the spirochetes, which apparently have some genetic relation with them. . . . These micro-organisms of Miller's are found in small numbers in almost every normal mouth, but usually only under the gum margins. [The organisms referred to were described by W. D. Miller, an American physician and dentist in Berlin, in 1883.]

H. Vincent (1862), military surgeon and bacteriologist, wrote "Sur une forme particulière d'angine diphtéroïde (angine à bacilles fusiformes) [On a Peculiar Form of Diphtheroid Angina (Angina with Fusiform Bacilli)]" in the *Bulletins et mémoires de la société médicale des hôpitaux de Paris* (15, 3rd series: 244-250, 1898). A portion of the translation follows:

This angina is characterized by a grayish or whitish pseudo-membranous exudate, by the associated fever and occasionally rather marked adenitis. . . .

If a bit of the pulpy exudate that appears on the surface of the pharynx is removed and stained with thionin or Ziehl's dilute fuchsin, microscopic examination shows two kinds of microbes to be predominant: a peculiar bacillus, easily recognizable by its length (about 10 to 12 microns) and its bulging central portion and distinctly tapering ends, and a delicate spirillum, more difficult to stain. This spirillum is quite similar to that normally present in the saliva and dental tartar.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

CASE HISTORY: FATAL PRENATAL SEPARATION OF THE PLACENTA

A thirty-seven-year-old gravida VI began to bleed when she was eight months pregnant, and was seen by her physician. The bleeding was painless; she was not in labor. No steps were taken until additional bleeding occurred, and she was sent to a hospital. In this institution, nothing whatsoever was done for her, and she was finally sent to another hospital, where she arrived nine and a half hours after the initial bleeding. On admission, the hemorrhage was brisk, the blood pressure was 72 systolic, 60 diastolic, and no fetal heart could be heard. A diagnosis of separated placenta was made. Vaginal examination revealed the cervix to be dilated sufficiently to admit one finger. The vagina and cervix were packed with gauze, and a Spanish windlass was applied. Intravenous

glucose was administered, but the patient was given no blood transfusion because no donor could be obtained. She died undelivered eight hours after entry to the second institution.

Comment. There is no information concerning the past history of this patient, and whether or not she had any prenatal care is unknown. Since there is no record of the blood pressure when she was first seen at home at the onset of bleeding and no statement of any urinalysis, it is not known whether the separation was associated with hypertension and albuminuria. The treatment accorded the patient by the physician who first saw her and by the hospital to which she was first sent is disgraceful: no examination was made, and she was not hospitalized until a second hemorrhage occurred. Her stay in the first hospital was merely a loss of time. Apparently, this institution was equipped neither professionally nor mechanically to deal with obstetric emergencies; the patient was untreated for at least two hours, and was then transferred to the second hospital. The treatment from then on cannot in any way be criticized, except for the fact that no transfusion was given. Patients with separated placenta who have a blood pressure of 72 systolic, 60 diastolic, and who have been bleeding for nine hours and continue to do so are very poor risks for laparotomy. The conservative treatment of packing the cervix and vagina and applying a Spanish windlass would in all probability have been successful had it been administered when the patient entered the first hospital.

The presence of plasma in most institutions helps materially in reducing the fatalities from hemorrhage when it is impossible to secure a blood donor.

DEATHS

LA MARCHE — WALTER J. LA MARCHE, M.D., of Cambridge, died May 30. He was in his eighty-first year.

Born in Belmont, Dr. La Marche received his degree from Laval University Medical Faculty, Montreal, and did postgraduate study in France. He was a former member of the Orthopedic Department, Massachusetts General Hospital, and of the staff of the Holy Ghost Hospital for Incurables, Cambridge. He had practiced in Massachusetts for over fifty years, and was a retired member of the Massachusetts Medical Society and the American Medical Association.

His widow, three sons and a granddaughter survive him.

SHULTIS — FREDERICK C. SHULTIS, M.D., of Leominster, died June 23. He was in his seventieth year.

Dr. Shultis received his degree from Dartmouth Medical School in 1897. He served on the staff of the Leominster Hospital. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

Two cousins survive him.

MASSACHUSETTS MEDICAL SERVICE

McCANN NAMED PRESIDENT BY BOARD

Dr. James C. McCann, of Worcester, was elected president of the Massachusetts Medical Service at the first meeting of the Board of Directors held at the Harvard Club in Boston on June 23. Serving as vice-president is Philip M. Morgan, president of the Morgan Construction Company, of Worcester. Edmund L. Twomey, attorney, of Newton, was elected treasurer. The Board meeting was the first step in a comprehensive program that will attempt to make the state-wide system for the

chusetts Safety Council and a member of the Executive Committee of the National Safety Council.

Mr. Twomey, treasurer, is a graduate of Holy Cross College and, in 1926, of Harvard Law School. He has practiced for many years with the Boston law firm of Palmer, Dodge, Barstow, Wilkins and Davis. He is married, has one son, and lives in Auburndale.

Pointing out that the medical profession is undertaking a radical departure from its previous mode of practice, Dr. McCann stated that the physicians are ready to accept their obligation in trying to solve the high cost of medical care accord-

DR. JAMES C. McCANN, President

MR. PHILIP M. MORGAN, Vice-President

budgeting of medical care available to the public shortly after September 1.

Dr. McCann has practiced surgery in Worcester since 1929. A native of Bangor, Maine, he graduated *magna cum laude* from Georgetown University in 1920, and from the Harvard Medical School in 1924. He received his Ph.D. in surgery at the Mayo Clinic of the University of Minnesota in 1929, and held a lieutenancy in the Army in 1918-1919. He is married and the father of six children.

Mr. Morgan, vice-president of the Massachusetts Medical Service, is a veteran of the first world war, a director of the Mechanics National Bank, of Worcester, and of the State Mutual Life Assurance Company, a trustee of Springfield College and Governor Dummer Academy, a director of the Massa-

ing to the American principles of democracy, at the same time maintaining the principle of private initiative and free practice.

"The launching of the Massachusetts Medical Service should lead to a very definite betterment of civilian morale," Dr. McCann said, "first, by the maintenance of health in industrial groups, and secondly, by assuring the families of the men in the armed forces that their medical-care burdens will be lightened."

Simultaneously, Dr. McCann announced that the Massachusetts Medical Society has established capital funds necessary to start the corporation in business and that Boston headquarters have been opened at 230 Congress Street. The corporation charter was granted by the State Commissioner of Insurance on May 27.

SUMMER PROGRAM

The first step in the summer program, according to Dr. McCann, is enrollment of the participating physicians. An attempt will be made for 100 per cent enrollment among the physicians remaining in civilian practice, and it is hoped that those going into the service will pledge their support.

The plan, as reported in the June 18 issue of the *Journal*, will provide budgeted payment of the full medical cost of hospital surgery, obstetrics and x-ray service for families with incomes not exceeding \$2500 yearly and for families with larger incomes on a cash indemnity basis. Later, it is proposed to extend the coverage and the benefits.

PHYSICIANS TO SERVE ON BOARD

Members of the medical profession are represented equally with laymen and subscriber representatives on the Board of Directors of the Massachusetts Medical Service.

In addition to Dr. McCann, who is serving as president, the physicians are Dr. J. Harper Blaisdell, Dr. Frank R. Ober and Dr. Samuel A. Robins, of Boston, and Dr. Charles E. Mongan, of Somerville. They have been appointed to the Central Professional Committee of the new nonprofit corporation.

Born in Providence, Dr. Blaisdell graduated from Dartmouth College in 1907 and from Harvard Medical School in 1911, and has practiced in Boston since 1914 as a dermatologist. Assistant dermatologist at the Massachusetts General Hospital for twelve years, he is now consulting dermatologist for the Winchester, Melrose, Malden, Haverhill and Exeter, New Hampshire, hospitals. He is a director of the Blue Cross and a member of the Council and the Committee on Public Relations of the Massachusetts Medical Society.

Retiring president of the Massachusetts Medical Society, Dr. Ober was born at Mt. Desert, Maine, and graduated from Tufts College Medical School in 1905. He came to Boston in 1914 as house surgeon at the Children's Hospital. Since 1937, he has been John B. and Buckminster Brown Clinical Professor of Orthopaedic Surgery at the Harvard Medical School; he is also assistant dean of graduate courses at the Harvard Medical School and professor of orthopedic surgery at the University of Vermont College of Medicine. He is surgeon-in-chief of the New England Peabody Home for Crippled Children and orthopedic surgeon at Peter Bent Brigham Hospital. He was a major in the Medical Corps, United States Army, in World War I and has been the editor or author of a number of medical volumes and papers.

Dr. Robins graduated from the Tufts College

Medical School in 1914 and did postgraduate work at the Tewksbury State Hospital and Boston City Hospital. Past president of the Greater Boston Medical Society, he is chief of the x-ray laboratories at the Beth Israel Hospital and was, for fifteen years, visiting roentgenologist of the Evangeline Booth and Boston Lying-in hospitals. He is a consulting roentgenologist to the Norwood Hospital and the Pratt Diagnostic Clinic. Clinical professor of radiology at Tufts College Medical School and instructor in radiology at Harvard Medical School, he is the author of numerous articles.

A member of the House of Delegates of the American Medical Association since 1921, Dr. Mongan received degrees of A.B. and A.M. from Boston College, and graduated from the Harvard Medical School in 1892. He did postgraduate work at the Rotunda Hospital, Dublin, and studied at Guys Hospital and the Brompton Hospital in London. Returning to Somerville as a general practitioner, Dr. Mongan has been a member of the senior staff of the Somerville Hospital since 1895 and is also a member of the staff of the Holy Ghost Hospital in Cambridge. He was the first president of the New England Obstetrical and Gynaecological Society and is a former president of the Massachusetts Medical Society. Recently, he was appointed by the Mayor of Somerville as chairman of the advisory committee studying matters concerning public welfare.

WAR ACTIVITIES

CIVILIAN DEFENSE

DECONTAMINATION SERVICES

The following letter has recently been released by the Office of Civilian Defense, Washington, D. C.:

The Office of Civilian Defense publications, *Protection Against Gas*, *First Aid in the Prevention and Treatment of Chemical Casualties* and *Handbook for Decontamination Squads*, outline the technics of decontamination. This letter sets forth the recommendations of the Office of Civilian Defense for the organization and administration of decontamination services.

DECONTAMINATION OF PERSONS

The decontamination of persons is the responsibility of the Emergency Medical Service. In cities within the target areas, facilities for decontamination of the wounded should be provided at or convenient to every hospital and casualty station. Facilities for the wounded should be separate from those for ambulant persons, because in a single station there will be a tendency to give priority treatment to the wounded while the ambulant become more severely burned.

It is not practicable for a city to provide complete decontamination services at the present time. Persons contaminated with liquid vesicants must be treated within five minutes to avoid severe burns; complete preparation would therefore require that facilities

be sufficiently numerous so that every individual is within five minutes walk of a decontamination station. Military authorities consider the use of gas against American cities unlikely, and the scarcity of materials precludes the possibility of extensive construction of decontamination facilities. It is desirable, however, that key personnel be trained and that plans be prepared so that facilities can be improvised and placed in operation on short notice, if necessary.

Decontamination stations should be of simple construction, with ample facilities for disrobing, bathing and chemical neutralization of agents that may have reached the skin. Wood is to be avoided in construction because it absorbs mustard gas and lewisite and is difficult to decontaminate. Brick, concrete or metal structures are preferable. All porous materials, including brick and concrete, should be painted with sodium silicate paint. Gasoline filling stations are widely distributed in most communities and offer many advantages in view of their isolation, washing facilities, and comparatively impervious construction. The Office of Civilian Defense will shortly issue plans indicating how filling stations may be adapted for this purpose.

The chief of Emergency Medical Service is responsible for organizing and training medical and other personnel to operate decontamination stations. Physicians and nurses must know how to protect themselves while handling contaminated cases, the effects of the various agents on the eyes, skin and respiratory tract, and measures for decontamination of the skin and eyes at various stages after exposure. Stations for ambulant personnel do not necessarily need a physician in attendance, but the person in charge should understand the dangers and limitations of chemical decontamination. He should also be on the alert for victims with respiratory tract, eye or severe skin exposure, who should be transferred to a hospital as soon as decontaminated. All members of emergency medical field units should be trained and drilled in decontamination.

The chief of Emergency Medical Service may appropriately request the local health department to establish and staff facilities for decontamination of uninjured persons. Public health nurses have experience in independent action and in handling groups of people, which fits them to supervise decontamination stations. Decontamination services organized and staffed by the health department for the decontamination of persons will operate as a branch of the Emergency Medical Service, under the commander of the Citizens Defense Corps.

DECONTAMINATION OF STREETS, BUILDINGS AND VEHICLES AND OF FOOD AND WATER SUPPLIES

The Office of Civilian Defense charts for the Citizens Defense Corps and the staff manual provide for decontamination squads as a part of the Emergency Public Works Service. The chief of Emergency Public Works Service has the responsibility for organization, training and administration of these squads. In their functioning their first task is rough decontamination of areas and of things in those areas. They will, in carrying out this function, use equipment, especially street flushing machines that presumably will be found in the public-works department of the usual municipality. Their first responsibility is the decontamination of streets, public buildings and the approaches thereto.

The inspection and testing for gas contamination and the decontamination of food and public water supplies are responsibilities of the municipal health department.

APPOINTMENT OF GAS OFFICERS

It is suggested that the commander of the Citizens Defense Corps appoint as a member of his staff, a senior gas officer, who will normally be chosen from the city health department. His functions will be to supply technical direction and assistance with respect to action to be taken before, during and after gas attacks. The duties of the senior gas officer are as follows:

During the period of preparation

- 1 He should become trained and familiar with the chemistry of war gases and the techniques and chemistry of decontamination. This information can be acquired from the Office of Civilian Defense publications and by attendance at the War Department civilian protection schools and at special schools being established by the Medical Division, Office of Civilian Defense in co-operation with the United States Public Health Service and the War Department schools.

- 2 He should recommend for appointment as assistant gas officers with qualifications similar to his own and train them to serve as his technical assistants to supervise decontamination of food and water.

- 3 He should with the chief of Emergency Medical Service select the sites for decontamination stations and provide consulting and technical service in the design and construction of these facilities.

- 4 He should instruct laundries in the technique of handling various types of contaminated clothing and arrange for the safe transfer of contaminated clothing from decontamination stations to laundries and for the return of clean clothing. For this purpose, he may appoint a laundry officer from the trade in the city.

During the period of operation

- 1 Identification of chemical agent or agents used in an area.

- 2 Determination of the extent of the area contaminated, and advice to wardens and police in the vicinity concerning the type of agent or agents and the extent of contamination.

- 3 Inspection and technical advice concerning the decontamination of streets and buildings and reports to the police and wardens when an area is safe for movement.

- 4 Inspection of food and water supplies, and supervision of proper measures for their decontamination. (In dealing with food and water supplies he should train and utilize the personnel of the municipal health department regularly employed for the supervision of food and water supplies.)

- 5 Collection and safe transportation to laundries of contaminated clothing and return of clean clothing to decontamination stations or hospitals (through laundry officer).

6. Inspection and technical control of decontamination of vehicles, equipment and machinery, including ambulances and other vehicles used in the transportation of casualties.

REPORT OF MEETING

NEW ENGLAND PATHOLOGICAL SOCIETY

A regular meeting of the New England Pathological Society was held on February 19 at the Massachusetts General Hospital.

Before and after the formal portion of the meeting an exhibit of pulmonary surgical specimens was demonstrated by Drs. Klopstock, Churchill and Castleman. The exhibit consisted of large watch-glass preparations, together with photographs and x-ray films of cases of bronchiectasis, lung abscess, cancer, bronchial adenoma, tuberculoma and tuberculous bronchial stenosis.

The first paper, "Subdural Abscess: A clinicopathologic study," was presented by Drs. Charles S. Kubik and Raymond D. Adams. The clinical features and pathological and surgical observations in 14 cases of subdural abscess were described. The sources of infection were paranasal sinusitis in 12 cases, otitis media in 1 case, and bronchiectasis with metastatic infection in 1 case. The symptoms in the cases in which abscess complicated sinusitis conformed to a fairly definite pattern: acute sinus infection, usually an exacerbation of chronic sinusitis; orbital swelling; pain or headache, at first localized, later becoming generalized and increasing in severity; rise in temperature, as a rule to 103°F. or higher; leukocytosis; stiffness of the neck; drowsiness, rapidly increasing to stupor and coma; and focal signs, which appeared at about the same time as drowsiness or stupor. Hemiparesis or hemiplegia occurred in every case. Paralysis of contralateral deviation of the eyes nearly always developed, and aphasia was observed in most cases of left-sided abscess. Jacksonian seizures were fairly common.

Spinal-fluid pressure, which was nearly always increased, ranged from normal to the equivalent of 350 mm. of water. Cell counts generally ranged from 150 to 600 per cubic millimeter, with polymorphonuclear leukocytes predominating, although in 1 case the count was 15 (lymphocytes) and in another 1200 (95 per cent polymorphonuclear leukocytes). The sugar content of the spinal fluid was normal. Chlorides were slightly decreased in 2 cases and normal in 2. The total protein ranged from 49 to 186 mg. per 100 cc. No organisms were found in smears or cultures.

Except for absence of sinus infection and orbital swelling, the clinical manifestations in the 2 other cases, secondary to otitis and bronchiectasis, respectively, were similar to those complicating sinusitis.

The course was rapidly progressive. In 12 cases, death occurred six to twenty days after onset of headache, and two to eight days after focal signs were first observed. In 2 cases, recovery took place after drainage of the abscess following a frontoparietal craniotomy.

In a majority of the 12 cases in which autopsy was performed, extension to the subdural space took place by direct extension through the dura; in the remainder, there was thrombophlebitis involving the venous sinuses, usually the superior longitudinal. The subdural pus in all cases covered the greater part of the lateral surfaces of the hemispheres, the greatest amount being situated over the lateral aspects of the frontal lobes. It was not encapsulated, although in some of the cases of old abscess, there was organization of the exudate on the inner surface of the dura. There was regularly a localized subarachnoid exudate,

conforming in its distribution to that of the subdural exudate, but scarcely any generalized meningitis. The frontal lobes beneath the abscesses were depressed, somewhat as with subdural hematoma, and in the underlying cortical gray matter there were severe ischemic necrosis and, in most cases, thrombosis or thrombophlebitis involving the subarachnoid veins.

It was pointed out that the clinical picture in each case was similar and that the diagnosis can therefore be made in time to save some of the patients. Drainage, it was thought, should be through a lateral frontal craniotomy opening, and not through the frontal sinus or a mastoidectomy wound. Performed in this way, the operation is simple and quick, and if the results are negative, little or no harm is done, provided that the brain is not explored. Once an empyema has developed, nothing is to be gained, and much may be lost, by operation on the sinuses or the mastoid. These may be taken care of later, if necessary, as was done in the 2 cases in which recovery took place.

The second paper, "Isolation of Pleuropneumonia-like Organisms from Human Patients," was presented by Drs. William E. Smith and Louis Dienes. In a consecutive series of cultures from the genital tract of 129 unselected patients, pleuropneumonia-like organisms were recovered from 23 of 77 cervical cultures, from 1 of 8 vaginal cultures, from 3 of 36 prostatic cultures and from 1 of 8 cultures of urethral discharges from men. It is apparent that these organisms are common inhabitants of the human genital tract. The question then arose whether they are saprophytes or pathogens.

The four male patients who yielded an abundant growth of these organisms all had chronic prostatitis. One had rheumatoid arthritis, 1 had polyarthritis clinically resembling gonococcal arthritis, and 1 complained of soreness of the feet and knees and swelling of the fingers. Specimens of synovial fluid were obtained from 2 of these patients, but no organisms could be demonstrated in them. Pleuropneumonia-like organisms were recovered in only 1 other case, that of a man who also had chronic prostatitis.

Among the women, considering only those in whom pleuropneumonia-like organisms were predominant, 5 had chronic cervicitis, 7 had gonorrhea, and in 4, the cervix appeared clean. One had a polyarthritis clinically resembling gonococcal arthritis, 1 had rheumatoid arthritis, and 3 complained of various skeletal aches and pains. Synovial fluid was obtained from the first-mentioned patient but was sterile. One of these patients was the wife of one of the male patients, a finding that suggests the possibility of transfer of the organisms by sexual intercourse.

In addition to the patients in this series, pleuropneumonia-like organisms were obtained from any cervical cultures and specimens from purulent complications. Several of these cases presented the clinical picture of acute gonococcal cervicitis. Cultures and smears were repeatedly negative for gonococci, but pleuropneumonia-like organisms were present in large numbers and in almost pure culture. One patient, an eighteen-year-old girl, developed an acute vaginitis with purulent discharge four days after intercourse. An abundant growth of pleuropneumonia-like organisms was recovered from this discharge. In another case, these organisms were recovered in pure culture from an abscess of Bartholin's gland. In a case of salpingitis, pleuropneumonia-like organisms and a few colonies of diphtheroids were cultivated from the pus expressed from the tubes. In a case of peritonitis secondary to salpingitis, an anaerobic bacillus (genus, *Bacteroides*) was obtained in pure culture from the peritoneal pus, and pleuropneumonia-like organisms were subsequently separated from the

cultures of this bacillus as a variant growth form. This patient made an uneventful and prompt recovery from her peritonitis, pleuropneumonia-like organisms were recovered from the cervix, indicating that the cervix had been the portal of entry of the infection. Gonococci could not be demonstrated in any of these cases.

The picture that is beginning to emerge from the evidence at hand is that pleuropneumonia-like organisms, like many other bacteria, may live in the genital tract without causing any obvious disease, however, they are capable of acting as pathogenic agents either alone or in combination with other bacteria. When they cause disease, they produce a clinical picture that is similar to gonococcal infection, in that a purulent discharge develops and such complications as abscess of Bartholin's gland, salpingitis and peritonitis may ensue. In men, these organisms have been found only in cases of chronic prostatitis. One must bear in mind the possibility that these strains may represent variant forms of bacteria, as suggested by Dr Dienes in the subsequent paper.

The incidence of arthritis in this series is of particular interest because arthritis is a common complication of both the natural and the experimental diseases produced in animals by organisms of this group. Dr Smith has not been able, however, to recover pleuropneumonia-like organisms from diseased joints, although a considerable number of specimens of joint fluids, synovial tissues and subcutaneous nodules from arthritic patients were examined.

The third paper, 'The Nature of Pleuropneumonia-like Organisms,' was presented by Dr Dienes. According to the generally accepted opinion, the etiologic agent of bovine pleuropneumonia and morphologically related organisms belong to a distinct class. The organisms of this group have characteristic physical properties, morphology and mode of reproduction. They are soft and have no rigid membranes. They show an extreme pleomorphism, growing from small filter passing granules and fine filaments into large soft bodies 20 microns or more in diameter. These large bodies take part in multiplication either by germination or by breaking down into small granules. These properties make it appear that there is no similarity in any essential characteristic between the pleuropneumonia-like group of organisms and ordinary bacteria.

It was therefore very surprising when an organism of the pleuropneumonia group was found in a bacterial culture (*Streptobacillus moniliformis*). This association is so close that the bacteria cannot be freed from the pleuropneumonia-like organism. The study of this association brought forward the following facts: the organism is not present in the bacterial cultures as a contaminant or symbiont but develops by the transformation of the bacteria, the two forms are serologically similar, reacting equally well with the agglutinating serum produced against either, and for a certain period after isolation, the pleuropneumonia-like forms easily revert into the bacterial forms. These facts make it certain that the connection between the two forms is not a bacterial association but that they are variant forms of the same organism.

Dr Dienes has observed similar variants in cultures of *Bacterium funduliformis*, a flavobacterium, *Haemophilus influenzae*, *Escherichia coli* and the gonococcus. He was able to separate the pleuropneumonia-like variants of *Bact. funduliformis* and the flavobacterium and to propagate them in pure culture.

On the basis of these observations, Dr Dienes believes that the organisms of the pleuropneumonia group do not constitute a class unrelated to the bacteria but that they represent a variant growth form of bacteria. With

S. moniliformis, this variation has been shown to be reversible. The colonies of the streptobacilli can be seen to produce the pleuropneumonia-like variant, which then breeds true on repeated subculture on agar plates, but re-produces streptobacilli when placed in broth. In other cases in which pleuropneumonia-like forms were produced by organisms such as *Bact. funduliformis* and the flavobacterium, the pleuropneumonia-like forms have not been observed to revert into bacterial forms but it should be added that these strains were only recently isolated and have not been intensively studied.

The observation of pleuropneumonia-like variants in cultures of several different bacteria and, in particular, of reversible variation in well studied cultures of *S. moniliformis* makes it reasonable to hypothesize that pleuropneumonia-like strains that show no relation to bacteria represent so-called fixed species which developed as non-reversing variant forms from ordinary bacterial organisms. For example, the organisms of bovine pleuropneumonia, agalactia and human strains appear to be such fixed species.

The discovery of this new type of bacterial variation may have considerable significance. The pleuropneumonia-like organisms are filterable, they are similar in staining properties to the viruses, and the diseases that they cause have usually been mistaken for virus diseases. Their further study may explain some of the unsolved problems of infectious diseases.

In the discussion of these two papers, Dr Tracy B Mallory emphasized the point that Dr Dienes had opened up a field of great potential value but that it is too early to see how great its practical importance is, although it may prove to be considerable. Some of these cases which Dr Smith had spoken of as vaginitis or cervicitis, were cases that clinically were believed to be characteristic of gonococcal infection. Dr Mallory said that he had seen two or three cases reported to the State Department of Public Health as gonorrhea, but the most careful check, both by symptoms and repeated cultures, always failed to reveal the gonococcus. It seems quite probable that these were false reports and that the cases represented infection with one of the pleuropneumonia-like organisms.

In answer to the question how the name 'pleuropneumonia' was arrived at, Dr Dienes explained that the first organism of this group to be discovered was the etiologic agent of bovine pleuropneumonia, a very serious disease of cattle in Europe. Since then, other organisms of similar morphology have been found and have been called pleuropneumonia-like organisms.

The last paper, Renal Biopsies from Hypertensive Patients, was presented by Dr Benjamin Castleman. During the past year he has had the unique opportunity of studying the renal tissues removed at biopsy from 70 patients during the course of splanchnic sympathectomies for the relief of hypertension. More than half the patients were under forty years of age, and the average age of the group was thirty-nine years. About two thirds of the group had normal renal function as measured by the phenolsulfonphthalein test. All but 3 cases showed definite vascular disease, the severity of which was classified into four groups, Grade I being the least involved and Grade IV the most. The arterial and arteriolar lesions were of old types: intimal hyalinization, medial hypertrophy and endothelial hyperplasia. Any individual case might show lesions of only one type or of combinations of them. An attempt was made to correlate the grade of vascular disease with the renal function and with the appearance of the eyegrounds. Although in most cases the degree of

renal disease compared favorably with the degree of renal function, in a few cases there were some inconsistencies. There was not, however, so good a correlation between the renal and the retinal vascular disease. For example, a few of the normal and Grade I renal disease cases had Grade III or IV eyeground changes. Although all but 3 cases showed renal vascular disease, it was not suggested that the vascular disease must necessarily precede the hypertension, because a large proportion of patients from whom biopsies are not available but who had the same radical operation (bilateral total splanchnic resection from the semilunar ganglion to approximately the midthoracic level and resection of the sympathetic trunk from the ninth dorsal to the first or second lumbar segment, inclusive) now have normal or almost normal blood pressure. In other words, many of these patients were benefited despite their renal disease. Dr. Castleman concluded that it was quite possible that the renal disease might be secondary to the hypertension and that, if the renal changes are only slight, sympathectomy might allow for a reversible reaction. If the renal vascular disease is severe, the anatomic changes are probably irreversible, but even in these cases clinical improvement may be very striking. One case was cited in which a second biopsy specimen, removed one year after the first from a twenty-seven-year-old woman, showed that, although the blood pressure, which was 235 systolic, 145 diastolic, before splanchnic resection, was then normal, the renal disease (Grade III) had not changed.

The discussion centered about the earliest changes noted in these cases, and Dr. Castleman stated that, although it has not been definitely proved, he believes that intimal hyalinization of the arterioles, rather than medial hypertrophy, may be the first anatomic evidence of hypertension.

BOOK REVIEWS

Roentgen Interpretation. By George W. Holmes, M.D., and Howard E. Ruggles, M.D. Sixth edition, thoroughly revised. 8°, cloth, 364 pp., with 246 illustrations. Philadelphia: Lea and Febiger, 1941. \$5.00.

When a textbook on a specialized subject requires six editions in twenty-two years it usually means either that there is a great demand for the book or that the subject matter is changing rapidly. Probably both facts are true of this work. The newest edition is largely the work of the senior author, Dr. Holmes, since Dr. Ruggles died in 1939, while the revision was being made.

This edition is again a concise, accurate statement of the important facts in diagnostic roentgenology, and has been brought up to date with many additions to text and illustrations. There are no unconfirmed or unreliable statements with which one can take issue, and only the time-tested and proved methods and principles are described and illustrated. Its short concise and conservative descriptions are models of accuracy and brevity and are in themselves an index of work based on analytic reasoning.

This is an excellent up-to-date presentation in textbook form of the principles and most of the details of roentgenologic interpretation. It does not pretend to be a complete or exhaustive treatise on all phases of the subject or an encyclopedia of roentgenologic diagnosis, and yet it is surprising how well the subject is covered in so little space. If anyone could learn and retain all the information between its covers, he would indeed be well equipped

to begin the practice of this specialty—lacking perhaps only the judgment born of long experience, some of which the author imparts to his reader.

There are but a few minor criticisms, which if heeded might make a good textbook even better: all the illustrations, unfortunately, are "positives," that is, the reverse in black and white of the original x-ray films—this is quite confusing to many students who are unable mentally to transpose the shadows to their original values; the index, which is after all one of the major parts of a textbook,—the can opener, one might say,—is rather scanty and in places incomplete; more of the illustrations could be clarified by a short description pointing out the salient features of the case or illustrations selected; and even greater benefit would accrue to the reader if the simple clinical facts or symptoms or the underlying pathologic process, could be tied in more frequently with the roentgenologic findings.

The typographic errors are but few and not serious. The references at the end of each chapter are largely to important source articles that give the details to those seeking further information. The printing, binding and mechanical details are excellently carried out, and the whole book is again the most valuable brief textbook of roentgenologic interpretation in the English language.

The Essentials of Occupational Diseases. By Jewett V. Reed, M.D., and A. K. Harcourt, M.D. 8°, cloth, 225 pp., with 1 chart. Springfield, Illinois: Charles C Thomas, 1941. \$4.50.

In this day of wartime industry, all physicians should know the hazards to which the worker is exposed, especially because substitution is bound to be prevalent for necessary materials formerly obtained from foreign sources. This small volume is an excellent compendium of such information.

The symptoms, diagnosis and treatment of occupational disease are considered. The first half of the book is devoted to chemical poisons; then, physical agents are described. Various industrial dermatoses, including cancer, are discussed. Occupational diseases of the lungs and infectious diseases are briefly summarized. A very abbreviated chapter on functional disturbances associated with occupational diseases affords an interesting ending for the book. Prevention, which the reviewer considers the most important phase in any study of occupation, is unfortunately omitted.

This handy reference book should be in the library of all physicians.

Theory of Occupational Therapy: For students and nurses. By Nora A. Haworth, M.A. (Cantab.), M.R.C.S., L.R.C.P., D.P.M., and E. Mary MacDonald. With a foreword by Sir Robert Stanton Woods, M.D., F.R.C.P. 8°, cloth, 132 pp., with 81 illustrations. Baltimore: Williams and Wilkins Company, 1941. \$2.00.

This practical manual, fully illustrated, gives a detailed account of the technic of occupational therapy as practiced in mental and other hospitals in Great Britain. Although the theory is stressed, much space is also given to the apparatus, finance, storage and similar problems. Written by authors of long experience, well known in America, this book is a welcome addition to the subject. The illustrations are particularly good.

NUMBER 2

THE RECOGNITION OF OCCUPATIONAL DERMATOSES*

C. GUY LANE, M.D.[†]

BOSTON

THE recognition of occupational dermatoses is a subject that needs review and requires some emphasis. Physicians are still too apt to think that because a person works at a certain job, any eruption he may develop is related to that job. Thus, the implication is that an eruption in a cement worker is due to cement, or that one occurring in a printer is due to turpentine. A physician is likely to be influenced by a worker who states at the first visit, "I got this rash from my job." It is also possible that, by failing to consider all the factors in a given case, a physician may deprive a worker of his just compensation or, on the other hand, permit a worker with a definite non-occupational dermatosis to receive compensation because of a wrong diagnosis.

The subject is particularly pertinent because of the present emergency. More men and women are being employed in newly created jobs. Therefore, many persons with limited training are at work on defense jobs. They may have been transferred from one job to another that uses substances which, to the workers at least, are new. They may have had some training for the job, but this training has not always concerned the dermatologic hazards, the prevention of skin injury, whether traumatic or chemical, or the care of the skin. The cry is for speed and more speed, and speed always paves the way for carelessness. The emphasis is on planes, tanks, guns and other defense items, and production is the main effort. Therefore, it can be expected that industrial accidents and diseases will increase, and with them will increase the occupational dermatoses, because 65 per cent of all industrial disease, according to figures obtainable at the present time, concern the skin. At present, in Massachusetts, approximately 300 cases of industrial dermatoses are reported each year; no doubt, an equal number or

more are not reported. In Ohio, 900 to 1000 cases a year are reported, and even in that efficient state there are undoubtedly more cases. A conservative estimate of 25,000 cases a year in this country can be made, but it is very easy to imagine that this figure will be doubled or tripled under present conditions.

If these figures are considered from the standpoint of disability, the item of "days' work lost" assumes almost alarming proportions. In Massachusetts, for one year, almost 20,000 days were lost because of occupational skin conditions. In Ohio, 39,000 days were lost in one year. Among federal employees, several years ago, 12,000 days were lost. In New York City, 40,000 days were lost in 1934. In a group of my own of 40 shoe workers whose disability was calculated, a total of over 1400 days was lost, the average being 35 and the longest 672 days. The disability from occupational dermatoses can accordingly constitute a real menace to production. Such disability may be partial or temporary, but it may be total and permanent as a result of industrial damage to the skin. It is easy to see that this menace can be as serious as sabotage or strikes in slowing up defense work, especially if trained personnel is affected. It behooves physicians, therefore, to be on the watch for such cases, and to look out for them as correctly and as justly as possible on the basis of all the facts in a given case.

One of the principal aims should be to detect these cases early, and thus to prevent the extension of the process and limit or prevent disability, not only for the good of the individual workmen but also for the sake of production in any particular factory. Early recognition also averts involvement of other workers because if a logical preventive program is carried out there will be a survey of materials and processes with which the workman is occupied, and there will be a change in the process or materials if it is possible, or at least preventive measures may be adopted before other pre-

*Read before a clinical meeting of the Maine Medical Association, Portland, October 17, 1941.

[†]Clinical professor of dermatology, Harvard Medical School; chief of Department of Dermatology, Massachusetts General Hospital.

sons are injured in the same way. Early detection gives an opportunity for prompt and proper treatment,—not only for the patient but also for the eradication of important causal factors. Thus, the abnormal condition will clear up more quickly, and the worker will be back on his job sooner.

A great opportunity is offered, in my opinion, to foremen, forewomen, industrial nurses and industrial physicians and surgeons, whether full or part time, to aid in this recognition of occupational dermatoses by early detection of the individual case. A similar opportunity is also offered to the general practitioner of medicine, especially in a manufacturing city. Many patients still prefer to go to their family physicians rather than to the physician or dispensary connected with their particular manufacturing plant. There are also many small shops that do not have any medical service. These foremen, nurses or physicians are all in the first line of defense against such hazards for the skin, and they should be aware of the responsibility for the early detection of *pathologic conditions of the skin for which occupational exposure can be shown to be a major, causal or contributory factor*—these words define well and briefly an occupational dermatosis.

In the dermatologic cases that fall into this group, certain significant items usually aid in the recognition of their status, both in the history and examination. Such items deserve more careful study because they point the way to the successful classification of the individual case. And such consideration of an occupational factor will be required, in all probability, in 15 to 20 per cent of all skin cases.

History

The usual procedure with any new or old case is to obtain a history of the present complaint, and in suspected occupational cases, an accurate history—not only of the existing manifestations but also of the occupation, substances handled, processes, cleansing methods and so forth—is of great value. The primary considerations, in my opinion, are questions on the duration and the site of involvement, both at the outset and subsequently. The duration has little special significance, for some cases may be acute and others chronic. But the site of the dermatosis assumes great consequence, especially if the hands or hands and arms alone are involved. If one is sure that the process is a dermatitis or eczema and not a disease such as lichen planus or erythema multiforme, it is really necessary to exclude an occupational factor as a cause, because the incidence of involvement of these sites is high in cases of dermatitis from occupational causes.

The onset and course of the disease may hold several important clues to occupational causation. The patient may observe that the beginning of the eruption was “due to his work,” but the physician should not be too greatly influenced by such a statement. In general, the site of onset is coincident with the site of maximum exposure or trauma. Furthermore, the time relation between exposure or trauma and the onset of the dermatosis should be correct for that particular dermatosis. Thus, an acute dermatitis should appear within a week after the exposure (although usually sooner), whereas a keloid may require several months, and a radiodermatitis a year or more. Another major consideration is the history of the course of the disease. If there is a story of several attacks of a similar type of dermatitis following exposure on return to a job, and remissions following layoffs, vacations or week ends, valuable evidence of an industrial causation is developed.

Somewhere in every dermatologic history, there should be a question on occupation, although the details need to be pursued only in cases that warrant it. In numerous occupations with a high degree of cutaneous hazards (Table 1), the details

Gardeners	

should be sought. On the other hand, a truck driver may require questioning on the details of his particular job. I have emphasized the need of two histories—one of the disease and the other of the occupational factors. This is usually a time-consuming procedure but usually pays large dividends.

Of particular interest in the occupational history are the agents used. Many different agents have been described as causal factors (Table 2), and

TABLE 2. Industrial Agents Frequently Producing Skin Disturbance.

Acids	Paints
Alkalies	Petroleum products
Dust	Paints and woods
Dyes	Rubber compounds
Metals	Solvents

new substances are constantly being employed in industry. If the patient being questioned is working with substances known to have produced many cases of skin disorder, more careful consideration

should be given to the possibility of an occupational dermatosis.

Attention should be directed not only toward the agents employed in the actual process, but

TABLE 3. *Cleansing Agents Frequently Producing Skin Disturbances.*

Water	Degreasing agents
Alkalies	Naphtha, gasoline and so forth

	Machine oil
	Paraffin oil

also toward the substances used as cleansing agents during or after working periods (Table 3), for these are often primary or contributing causes.

Two other questions should be included if any suspicion of occupational causation is aroused. The first concerns the involvement of the skin of other workers at the same job as that of the patient being questioned. Such eruptions may be coincidental, but the matter deserves further consideration. The second question or set of questions should include possible *nonoccupational* contacts or trauma that might cause a skin disturbance similar to the one presented by the patient. Thus, the questions in a case of dermatitis might cover exposure to poison ivy, painting at home, cementing for a neighbor, part-time work developing photographs and so forth. Such a history casts definite doubt on the occupational process as the sole causative factor.

In any history, dermatologic or otherwise, there should be queries concerning therapy, both external and internal. Numerous drugs may produce eruptions, and occupational or other skin disease is frequently masked, altered or exaggerated by local applications. Twenty-five per cent of all dermatitis may be of therapeutic origin, and it may consequently be difficult to evaluate the original condition of the skin.

In summary, the recognition of an occupational dermatosis depends in part on the careful evaluation of certain factors obtained by questioning—the site of onset, course, time relation, details of occupation, agents handled, cleansing substances used, status of fellow workers and possible non-occupational contacts.

Examination

In the examination of the patient, certain other factors must be weighed. In the first place, the site or sites of maximum involvement should be noted. In occupational cases, these sites coincide generally with the sites of maximum exposure to a

particular substance, and any discrepancy requires careful study.

Secondly, the types of lesions should be noted. A careful inspection should be made of the color, arrangement and so forth, together with such other general examination as is necessary to make a correct diagnosis, if possible. If a definite causal factor is suspected, the dermatosis should in general consist of lesions described in similar cases previously reported. Thus, one does not expect to find in a shoe treer the type of lesions and arrangement seen following contact with poison ivy.

Inspection should also reveal the stigmas of the patient's occupation—that is, the calluses produced by pressure and friction, the stains and pigmentation caused by materials used in his work and so forth. Such findings give additional evidence of the occupation and aid in confirmation of other findings.

At the same time, a healthy suspicion should cause the physician to be on the watch for other skin disease, nonoccupational as well as occupational. The finding of patches of psoriasis on an elbow or the presence of scars suggesting syphilis necessitates a review of other findings.

Further examination by pertinent laboratory work, biopsy, cultures, serologic tests, microscopic study of scales or pus and so forth should be carried out, if necessary.

In cases of dermatitis, patch tests with the suspected material offer a means of identifying the etiologic agent, even though the results of such tests are overemphasized at present. Numerous false-positive and false-negative reactions are reported, perhaps partly from variations in technic and interpretation. Patch tests, by themselves, should be regarded as confirmatory of the history and examination and not as diagnostic. It is necessary that they be properly performed by accepted procedure and correctly interpreted by physicians with adequate training in this field to have the proper value in the estimation of an occupational cause.

Diagnosis

After such a history and examination, the next step is the dermatologic diagnosis, without regard to the occupational factor. In other words, Is the correct diagnosis of the patient at hand dermatitis, carcinoma, lupus vulgaris or lichen planus? If the diagnosis is a disease in which there has been no previously described occupational factor to the best of one's knowledge and belief, it can be said that occupational dermatitis need not be considered. Thus, lichen planus, erythema multiforme, scabies, alopecia areata and so forth can be regarded as nonoccupational dermatoses. If the

condition is recognized as one in which previous cases have been shown to be of occupational origin, some of which are shown in Table 4, the

decision must be made regarding the diagnosis of an occupational dermatosis and the recognition of the causal factor or factors. It is not enough to make a diagnosis of an occupational dermatosis,—acne, keloid or folliculitis,—for it is essential for the development of proper preventive measures

to detect the cause. These causes are manifold, and much space would be required to list them all. Their wide variation is indicated in Table 5.

In the search for causes, not only is a careful review of the history and the examination essential but much is contributed by a knowledge of previous literature on the subject. It may be necessary to inspect the process, to interview the foreman, chemist, nurse or manager, and to perform patch tests, chemical investigations and bacteriologic and pathological studies to confirm the ultimate cause. In numerous cases, it is desirable to make full use of the facilities of the Laboratory of Dermatoses Investigation of the United States Public Health Service in Washington and the Council on Industrial Health of the American Medical Association for a solution of individual problems.

Diagnostic Difficulties

In discussing this subject, I am aware of the obstacles that present themselves: the language difficulties, the intelligence and co-operation of the patient affected, or rather, the absence of them, the lack of accurate knowledge of the average employee of processes and materials, the long duration of disease before a competent opinion is

obtained, the previous and often excessive treatment, the fact that other agents may cause similar manifestations, and the apathy or possibly the dislike of some manufacturers to disclose trade formulas and other secret information.

I am also cognizant of the obstacles in diagnosis for the industrial physician or general practitioner who has had dermatologic training only in his regular medical-school course. There is enough difficulty for the trained dermatologist in many cases. General practitioners see a relatively small number of cases of the same disease, whether it is scabies, lichen planus or lupus erythematosus. It is natural, therefore, that they will not have a familiarity with the atypical and borderline manifestations, and especially the overtreated cases. Moreover, many physicians lack the knowledge of the actual ingredients that the worker is using and of the processes employed.

Furthermore, I am aware of the difficulty encountered in rendering a clear-cut opinion of occupational or nonoccupational liability in every case, for many cases must be classified as "probably" or even "possibly" industrial. In addition, in some states, only certain diseases are listed in a category legally acceptable for compensation. In other states, compensation is granted for complications of occupational dermatoses or for exaggeration by occupation of existing skin disease.

There is thus a definite need for the adoption of more uniform legislation covering this field, for a more systematic review of suspected cases, for the establishment of acceptable standards of definition, criteria and so forth, and for the development of well-standardized preventive measures that can be universally adopted. Wide publicity must be given to the fact that occupational diseases in general are preventable and that the fullest use of accepted medical procedures will definitely aid in the recognition of this group and thus prevent not only disability of the patient but also possible serious disturbance to industrial production.

SUMMARY AND CONCLUSIONS

Emphasis is placed on items in the history and examination that may aid in the recognition of occupational dermatoses.

Early detection is stressed as a most valuable aid in preventive measures.

Some of the causes and manifestations of occupational dermatoses are reviewed, and some of the difficulties in deciding these cases discussed.

The belief is expressed that a more careful consideration of this group of patients will enable physicians to recognize the occupational cases earlier and thus render better service to patients and to industry.

THERAPEUTIC EVALUATION OF TESTOSTERONE IN PERIPHERAL VASCULAR DISEASE*

SAMUEL B. BEASER, MD,† AND THODORE B. MASSELL, MD‡

BOSTON

THE diversity of opinion regarding the value of the numerous forms of therapy in current use for peripheral vascular disease, we believe, is due to the inadequacy of the tests of circulatory function so far utilized.

Walking is a reliable quantitative test of function if judged on the basis of capacity to walk until pain occurs. It is an easily repeated measurement of tolerance and is capable of standardization. It does not involve the use of special apparatus, and it tests muscles that the average elderly patient is accustomed to using—in other words, it constitutes a normal activity for the patients concerned.

Chronic progressive occlusion of the vascular supply to an extremity proceeds in three stages: the long preliminary period free of symptoms, except perhaps absence of pulsations in the dorsalis pedis artery; the interval of intermittent claudication, when the blood flow has been reduced by fully two thirds,¹ which continues for months or years until further substantial reduction in blood supply is obtained; and the final period, which is characterized by trophic disturbances in the skin, rubor and, eventually, skin infection.

The patient usually seeks relief in the second stage. Therapy is generally intended to promote improvement in the circulation of the muscles by vasodilating or other agents, which act presumably by encouraging an increased flow in the collateral vessels. Since the vascular supply to the skin stems from the deep (muscular) vessels, postponement of the superficial tissue breakdown that leads to gangrene and amputation may be achieved.

Measurement of an increase in the circulation of the deep vessels is not directly appraised by the methods in common use. The oscillometer measures pulsations in the large vessels. The plethysmograph cannot be easily adapted for routine clinical study. The muscle-temperature thermocouple is not useful for the measurement of the necessarily slow improvement that may occur. Skin-temperature measurements and immersion calorimetry deal essentially with changes in superficial vessels, and there is much evidence to indicate a dissociation in the response of deep and superficial vessels to drugs.²

The therapeutic agent tested in this study for its effect on circulatory function was testosterone propionate. The drug was first suggested by Arndt³ in 1939 for the relief of intermittent claudication. This author describes a favorable effect on this condition in 6 men, but the evaluation was based entirely on a general statement by the patient that he felt better. The duration of improvement was not given, and in 2 patients smoking was decreased or eliminated during the period of treatment.

Subsequently, Edwards et al⁴ reported that testosterone produced "marked improvement in the walking ability of all the patients, with delay or abolition of the intermittent claudication." The patients were followed for several months, but no mention was made of other therapeutic procedures that may have been used simultaneously, nor was any objective measure of evaluation used.

In our study, the walking test was performed in a level, unobstructed hospital corridor, which was kept at a nearly constant temperature of 72°F during most of the year. An increase over this temperature in the summer did not seem to affect the performance of the patients.

They were paced at a constant rate of 88 yards a minute. In only 1 patient, who had definite peripheral arterial disease, was a faster pace necessary to bring on symptoms of claudication. They were asked to indicate, as they walked, the moment when tightness or cramps in the calf muscles appeared, but they continued to walk until the severity of the pain required them to stop. Those patients who at this moderate pace experienced angina pectoris or severe dyspnea before the onset of claudication were excluded from study.

Our series consisted of 6 men between the ages of forty-five and sixty-two years, all of whom had had intermittent claudication for from six months to seven years and were under observation in our clinic most of the time. One patient had thromboangitis obliterans, and the remainder had arteriosclerosis; 1 of these also had diabetes mellitus. Each patient presented objective evidence of peripheral vascular disease: absent arterial pulsations, and color and temperature changes in the feet. Previous to observation, 2 had ceased smoking, and 2 had not, 5 had had Buerger's exercises, and 4 intravenous 5 per cent saline injections, with no defi-

nite evidence of improvement subjectively or objectively.

In each case, a level walking test was performed weekly until three consecutive tests showed similar results. During the initial period of observation, all patients were given intramuscular injections of 1 cc. of physiologic saline solution. All other aspects of the care of these patients were unchanged, such as exercises and the use of tobacco and alcohol.

After a control period of four observations during at least one month, intramuscular injections of testosterone* were started. These were given three times a week—in 2 patients for six weeks, and in the remaining 4 patients for from three to six months. The total weekly dosage varied from 30 to 225 mg., averaging 100 to 125 mg. In addition to the intramuscular therapy, 3 patients were given the hormone by inunction daily for three weeks to a total dose of 50 mg.

In all the cases except one, the objective walking test showed no improvement in spite of occasional assertions of subjective improvement by the patient. This patient did not improve after doses of 15 to 150 mg. a week for ten weeks, but had a slightly increased walking tolerance after five additional weeks with doses of 225 mg. a week. The

The patients were not told the nature of the medication administered, but were questioned regarding possible effects of the treatment on sexual activity. One claimed an increased libido, but continued impotent.

DISCUSSION

Neither Arndt³ nor Edwards⁴ offered any explanation of the mechanism by which the improvement claimed from the use of testosterone was accomplished. Edwards et al.⁵ stated that there was an increase in oxygenation of hemoglobin in the cutaneous vessels of eunuchoids and castrates following the administration of androgenic substance. A possible explanation for the fact that some of their patients reported subjective improvement in walking ability is found in the recent reports that these preparations decrease muscular fatigability in eunuchoids.⁶ However, none of our patients with peripheral vascular disease and none of those of Arndt and Edwards exhibited any of the characteristics of testicular insufficiency. It is doubtful whether observations on eunuchoids or castrates can be applied to the normal elderly man.

SUMMARY

Measurement of a patient's ability to walk on a level surface at a given rate until the onset of claudication is a satisfactory method of evaluating peripheral circulatory function in ambulatory patients with peripheral vascular disease.

Using the above test, it was found that testosterone propionate, in dosages up to 150 mg. a week, did not prevent intermittent claudication in the lower limbs of 6 patients with occlusive vascular disease.

CLINICAL NOTES

HEMORRHAGE FROM A RUPTURED CORPUS LUTEUM*

REPORT OF A CASE IN A TWELVE-YEAR-OLD GIRL

PHILIP S FOISIE, MD†

BOSTON

INTRA-ABDOMINAL ovarian hemorrhage in nongravid patients has in recent years become recognized as a fairly common occurrence. Exclusive of cases due to a demonstrable lesion, there are a fairly large number in which hemorrhage of varying degrees occurs from apparently normal ovaries. These patients can be divided into two groups: those with a ruptured graafian follicle and those with a ruptured corpus luteum. The symptoms in these two groups differ chiefly in their relation to the menstrual cycle and in their severity. Rupture of the graafian follicle is a normal physiologic process that occurs in the mid-menstrual period and in which hemorrhage is rarely severe. Rupture of the corpus luteum is not physiologic, occurs in the premenstrual period and produces hemorrhage that may attain fatal proportions.

A review of the literature of the last fifteen years shows that there are now several hundred of such cases on record, with an age incidence anywhere during the childbearing period but rarely during the early years of that period. Hoyt and Meigs,¹ in 1936, reported a series of 58 cases, the youngest patient being fourteen years old. In the same year, King and Hawes² reported a case in a twelve year old girl in whom menstruation had begun one year earlier, at the age of eleven. The occurrence, therefore, of a case of hemorrhage of an exsanguinating degree in a girl of twelve whose catamenia began only a month before seems to be worth reporting to emphasize the necessity of considering this diagnosis at any time after puberty, even when the patient may be regarded as a child rather than a childbearing woman.

Before mentioning the details of this case, I shall review very briefly the normal physiology of ovulation. The ovaries are made up largely of a number of ova, and as any particular ovum matures, it approaches the periphery of the ovary, whose surface becomes prepared for its extrusion by a thinning-out process that reduces its vascularity. Physiologic rupture of the graafian follicle then occurs, with escape of the ovum, constituting ovulation and taking place at about the middle of the menstrual cycle. Usually, only a small amount

of serum escapes in this process, but sometimes a mild degree of bleeding also occurs that causes varying degrees of discomfort in the lower abdomen and not infrequently results in an erroneous diagnosis of acute appendicitis. Europeans seem to have more trouble with this condition than Americans; at least, it is talked of a good deal more in foreign literature and is what the Germans refer to as *Mittelschmerz*. Although varying degrees of hemorrhage may take place in this process, such bleeding rarely reaches alarming proportions, and conservative treatment is indicated.

Following ovulation, the ruptured graafian follicle seals up again and develops the yellow luteal cells that give it the name of corpus luteum. If impregnation does not occur, the corpus luteum rapidly degenerates, forming a white scar—the corpus albicans. Rupture of a corpus luteum causes hemorrhage that may reach fatal proportions. This occurs in the premenstrual period, a day or two before the onset of the next menses. Hemorrhage may be so extensive in these cases as to give signs of diffuse abdominal pain, nausea and vomiting, marked abdominal spasm and general evidence of severe blood loss. This picture is usually confused with that of a rupture in an ectopic pregnancy or in the less severe cases with acute appendicitis. The incidence seems to be definitely greater on the right side, and this, of course, adds to the confusion with appendicitis; moreover, symptoms are often referred to the right side even when the left ovary is involved.

The following case is interesting because the patient was a child whose catamenia had begun just one month before her illness. This patient had had only one previous corpus luteum that could have ruptured, and is therefore only one month removed from the earliest possible occurrence of the accident physiologically.

CASE REPORT

F O H (BCH 939366), a 12 year old girl was admitted to the hospital on May 7, 1939, with a complaint of abdominal pain. The first catamenia began 1 month before admission and lasted 5 days, with considerable cramps. The second period was due at the time of admission.

The patient had had measles, whooping cough and scarlet fever. The tonsils and adenoids had been removed 6 years previously.

The patient stated that the evening before admission she had a heavy supper consisting of baked beans, frankfurters, pickles, cake and milk, and that she awoke in the middle of the night with abdominal pain and nausea, she vomited about 4 a.m. and continued to be nauseated, and vomited during the rest of the night and the next morning. When she entered the hospital in the afternoon, it was stated that there were no abdominal signs. Examination of the urine showed 10 to 12 white blood corpuscles per high power field, and the patient was admitted on a medical service with a diagnosis of pyelitis. She continued to have abdominal distress and nausea, and gradually during the latter part of that day, abdominal

*From the Fourth Surgical Service, Boston City Hospital.

†Assistant in surgery, Tufts College Medical School; assistant to a visiting surgeon, Boston City Hospital.

signs became more apparent. Toward midnight, surgical consultation was requested, and I saw her about 1 a.m. The abdomen was distended throughout, with considerable spasm and marked tenderness in both upper quadrants, particularly the left. In addition, the patient presented the picture of acute blood loss. The blood pressure was 90/54. The red-cell count was 2,400,000 with a hemoglobin of 45 per cent, and the white-cell count was 17,000, with a shift to the left. The nonprotein nitrogen was 48 mg. per 100 cc. Examination of the urine showed an acid reaction, a specific gravity of 1.017, a + test for albumin and 10 white cells per high-power field. The vomitus showed a +++ test with benzidine.

Because of the unmistakable evidence of severe blood loss, the absence of any history of trauma and, most particularly, the onset in the premenstrual phase, a preoperative diagnosis of ovarian hemorrhage was made. The patient was given a 500-cc. transfusion, following which it was apparent that bleeding was continuing, and she was operated on about 3 a.m. under cyclopropane anesthesia. When exposed, the peritoneum was distended with dark blood, and the distention was so severe that this layer could not be picked up with an ordinary mouse-tooth forceps. When the abdomen was opened, large clots and free blood burst forth, thus giving evidence of old and fresh bleeding. The right tube and ovary were normal. The left ovary had been split wide open, so that only a shell remained. There was active bleeding from the inner surface of this shell. The ovary was clamped and removed, and the abdomen closed without drainage after all clots had been removed.

On the day following operation, the temperature rose to 104°F.; the pulse was 160, and the patient appeared to be moribund. She was put in an oxygen tent, two additional transfusions were given, and she promptly rallied. On the 3rd day after operation, she appeared to be definitely recovering. She made a normal convalescence and left the hospital in excellent condition on the 9th postoperative day.

This case could hardly have been distinguished preoperatively from a ruptured tubal pregnancy, except of course that the youth of the patient made this diagnosis improbable. It should be noted that Cullen's sign was not present, although the abdomen was extremely distended with dark clotted blood.

SUMMARY

The physiologically earliest case on record of intraperitoneal hemorrhage from ruptured corpus luteum is reported. It is emphasized that this condition must be considered in all females in the childbearing period who present acute abdominal signs.

Rupture of the graafian follicle, which is a normal physiologic process occurring in the midmenstrual period, may be accompanied by mild bleeding and may be confused with appendicitis.

Hemorrhage from a ruptured corpus luteum occurs in the premenstrual period and may be accompanied by severe hemorrhage, which may simulate almost any diagnosis connoting an acute

condition of the abdomen, most commonly acute appendicitis and rupture in an ectopic pregnancy.

THE USE OF SULFANILAMIDE FOR THE TREATMENT OF AN INFECTION DUE TO MICROAEROPHILIC STREPTOCOCCI

REPORT OF A CASE

ALFRED HURWITZ, M.D.*
AND EDWIN L. PRIEN, M.D.†

BOSTON

BURROWING subcutaneous infections caused by microaerophilic streptococci constitute a clinical entity characterized by extensive destruction and undermining of the skin and subcutaneous tissues. Topical antiseptics were found useless until Meleney¹ developed the zinc peroxide method of therapy.

The local use of chemotherapeutic agents has been described by Jensen, Johnsrud and Nelson² and Key and Frankel³ and has been employed with good results in the treatment of war wounds in England. Schneider⁴ successfully treated an undermining infection of the right thigh due to *Staphylococcus aureus* and microaerophilic streptococci with hydrogen peroxide and sulfanilamide locally. Meleney and Harvey⁵ reported favorable but not striking results with the use of zinc peroxide locally and sulfanilamide orally in the treatment of burrowing infections caused by *Streptococcus haemolyticus* of the microaerophilic type.

In the following case, the zinc peroxide method failed, but sulfanilamide powder rapidly effected a cure.

CASE REPORT

First admission. J. W., a 48-year-old man, was admitted on July 22, 1940, because of multiple draining sinuses in the left groin. The condition began as a small "pimple," which had been incised. A purulent discharge developed, and multiple sinuses soon formed. The condition became progressively worse. On admission, the patient presented an indurated area in the left groin, and the perineum contained multiple sinuses from which a profuse purulent discharge issued.

*Assistant in surgery, Harvard Medical School; assistant in surgery, Beth Israel Hospital.

†Associate neurologist, Newton Hospital; assistant neurologist, Boston Lying-in Hospital.

Cultures from the wound revealed diphtheroids, a non-hemolytic streptococcus, *Staphylococcus albus* and *Escherichia coli*. The Frei test for lymphogranuloma inguinale was questionably positive on one occasion, but negative when repeated. No tubercle bacilli or fungi were found. The blood Hinton and Kahn reactions were negative.

The clinical course was characterized by a low-grade fever not exceeding 100°F. The red-cell count was 3,500,000, and the white-cell count averaged 20,000. After 5 days of oral sulfanilamide therapy, extensive incision and drainage were performed. Boric acid dressings and irrigations were used postoperatively, and the wound gradually healed, so that after 55 days it was approximately half closed and covered by healthy granulation tissue.

The patient was discharged to his home under the care of a nurse, who continued the boric acid dressings. After 3 weeks, she noted that the wound failed to improve.

Second admission. When readmitted on October 31, the patient appeared chronically ill. The wound was covered with a dull-gray granulation, a purulent exudate escaping from beneath the skin margins. Undermining extended over a wide area from side to side, beginning at the left anterosuperior iliac spine and extending to the right beyond the right rectus abdominis muscle (Fig. 1) and from

aeruginosa (Bacillus pyocyaneus) and, for the first time, a microaerophilic hemolytic streptococcus.

A radical excision was made with the electric cautery. The overhanging skin margins were excised back to healthy tissue except in the penile area, where little could be done except to widen the entrance to the recess. Both spermatic cords were uncovered. There was evidence of burrowing beneath the left cord, but no excision was made. In its widest extent, the wound measured about 28 cm. transversely. Most of the skin and subcutaneous tissue

above downward beginning about 6 cm. below the umbilicus and extending over the medial aspect of the left thigh, including the area of the adductor canal and the tissue in the fold between the thigh and the scrotum as far back as the junction of the scrotum with the perineum. The process had also worked its way over the symphysis pubis in the midline and had invaded the areolar tissue between the symphysis and the dorsum of the penis so as to lay bare the sheath of the corpus spongiosum. A deep recess was formed in this way.

Laboratory data revealed a white-cell count of 18,300, a red-cell count of 3,470,000 and a hemoglobin of 58 per cent. Culture from the wound showed *Pseudomonas*

FIGURE 2. Wound about Six Weeks after Sulfanilamide Was Employed Locally and about Four Weeks after Grafting.

of the abdomen below the level of the umbilicus and of the medial aspect of the thigh over the adductor canal was removed. The pendulous portion of the penis sagged somewhat because its supporting tissues had been cut away, but the spermatic cords served to stabilize the penis and anterior scrotum.

Zinc peroxide dressings were applied daily, with considerable improvement at first. After several weeks of this treatment, it was found that the zinc peroxide was not being prepared according to the specific directions of Meloney. This was remedied, but the lesion did not improve. The granulations became gray, and there was evidence of further burrowing of the process into the tissues about the left femoral artery in the groin. Anaerobic cultures were made through the courtesy of Dr. Champ Lyons, of the Massachusetts General Hospital, who reported that the hemolytic streptococcus did not belong to Group A, B or C of Lancefield and was therefore not likely to respond to sulfanilamide therapy.

On December 24, a spontaneous perforation of the left femoral artery occurred about 5 cm. below Poupart's ligament. Prompt action by an intern, who placed a clamp over the vessel just above the perforation, saved the patient's life. The artery was exposed with some difficulty because of the surrounding granulation tissue and was securely ligated. Transfusion of 1000 cc. of citrated blood from the hospital blood bank was given soon afterward.

The perforation had occurred above the junction of the profunda artery with the femoral, and the leg became cold rapidly. Paravertebral novocain block was not attempted because of the precarious condition of the patient. Fifteen hours after the accident, a line of demarcation appeared at the level of the mid-dorsum of the foot.

On the following day, the wound was sprayed with 2 gm. of sulfanilamide powder. This was repeated daily. Improvement was noted in the wound 24 hours after the first application of the powder. The granulations became red, and the wound closed in rapidly. After 2 weeks of sulfanilamide therapy, the wound was covered with pinch grafts, which were sprayed with sulfanilamide powder 48 hours afterward. Complete epithelialization was achieved after 6 weeks (Fig. 2).

On January 22, 1941, an open amputation of the toes and heads of the metatarsals of the left foot was performed because of gangrene and low-grade infection, and 2 gm. of sulfanilamide powder was sprayed into the stump tissues. A plaster-of-Paris shell was applied to immobilize the extremity. The foot dressing was left untouched for 9 days. Thereafter, the stump was sprayed with sulfanilamide powder about three times weekly. Sulfathiazole, 4 gm. daily, was started 2 days before the amputation was done and continued for 15 days. Thus, the patient

received sulfanilamide locally in the wound and sulfathiazole by mouth coincidentally. Convalescence was uneventful except for a pressure ulcer on the heel.

The patient was discharged improved on February 26. Since then, he has made steady progress.

SUMMARY

A case of infection due to a hemolytic streptococcus of the microaerophilic type and treated successfully with sulfanilamide locally after zinc peroxide therapy had failed is reported.

MEDICAL PROGRESS

PHYSICAL THERAPY FOR DISEASES OF THE NERVOUS SYSTEM

ARTHUR L. WATKINS, M.D.*

BOSTON

THE treatment of patients with disorders of the neuromuscular apparatus constitutes a large proportion of the practice of physical medicine. The type of treatment used depends on the symptomatology present rather than the etiologic agent, since there are no specific curative physical measures. Consequently, diseases producing similar clinical symptoms and signs are grouped together, and the applicable physical-therapeutic measures outlined. The Kenny method of treatment of infantile paralysis has received so much publicity and interest that it is considered separately in more detail.

KENNY TREATMENT OF POLIOMYELITIS

The National Foundation for Infantile Paralysis has recently sponsored a course in physical therapy based on the Kenny method of treatment of infantile paralysis in the acute stage. This was given in Minneapolis by Drs. Cole, Knapp, Pohl and

others at the University of Minnesota. Sister Kenny and her associates demonstrated their method of treatment, and the original cases treated by her in this country were examined. This report is based on information obtained through this course and from the recent literature.¹⁻⁵

Before the results of the Kenny method are discussed, the traditional treatment of poliomyelitis, although not standardized, will be briefly outlined for the sake of comparison. The accepted opinion has been that, in poliomyelitis, flaccid paralysis of muscles occurs from destruction of the anterior-horn cells. In some cases, one group of muscles is thought to be more affected than its antagonist, so that the weaker muscles tend to be stretched by the pull of the stronger ones, with resulting deformities. The general principle of treatment is rest of the weak muscles by immobilization with splints designed to keep the stronger muscles stretched and to prevent tension on the weaker ones. Local applications of heat may be given one to three times a day in the acute stage to painful tender muscles. There is great variation in different institutions in the duration of the immobilization period. It may extend as long as eight weeks,

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

*Assistant in medicine, Harvard Medical School; director of the Physical Therapy Department, Massachusetts General Hospital.

or in some cases, passive and active motion may be allowed from the beginning. When muscles are no longer tender, a detailed, functional muscle examination is done, and splints are adjusted to protect weaker muscles. Muscle re-education, which is then begun, consists of exercises designed to strengthen the weaker muscles with some active and passive painless stretching of the tight contracted muscles. This muscle training may be done on a table or under water, the splints being maintained between treatments.

The Kenny method of treatment is based on different concepts of the symptomatology and the factors that lead to the development of deformities. Sister Kenny admits that there will be a certain variable percentage of patients with a residual flaccid paralysis of one or more extremities. This is a result of complete anterior horn cell destruction, for which there is no known cure, and she does not claim cures. Her treatment is directed toward another condition, which she calls muscle 'spasm'. This symptom is thought to be of the utmost significance because, if it is not treated early, contracture, fibrosis, atrophy and loss of function result. This so-called "spasm" consists in pain, tenderness on pressure, constant hyperirritability particularly on stretching, and, in some cases, visible fasciculation. After several weeks, muscles that have been thus affected and not treated properly exhibit contracture, fibrosis and atrophy. Her term "spasm" refers in a general way to these conditions, and is misleading if interpreted according to accepted usage.

She has further observed that, in the majority of cases, the posterior muscles of the neck, trunk and lower extremities are more affected by "spasm" than the anterior muscles with antagonistic action. She believes that the antagonists of the muscles with 'spasm, if treated in the traditional manner, become lengthened and atrophied from disuse, and finally, that power of voluntary contraction is lost. She designates such a functionally paralyzed muscle as 'alienated'. She also speaks of it as 'non-paralytic', meaning that if the "spasm" of its antagonist is released and it is allowed to regain its proper resting length it may be made to function by proper stimulation and re-education. She has learned to distinguish a truly paralyzed muscle from an 'alienated' one by passively stretching the muscle repeatedly a few times within a small range of motion, then, by careful observation, a functionally paralyzed muscle will be seen to develop tension so that its tendon will stand out beneath the skin. One might explain this by the assumption that the myostatic stretch reflex had been thus elicited.

A third factor leading to muscular dysfunction has been described by Sister Kenny and called

inco-ordination. This consists in the substitution of accessory muscles or even antagonists for the proper prime movers of a joint. Individual muscles are also said to contract improperly in sections rather than through their full length, and again this is spoken of as "inco-ordination." This phenomenon, I believe, is at least in part generally recognized to occur whenever there is attempted motion of a joint by partially paralyzed muscles, particularly if such motion is painful, and also following immobilization.

The Kenny method of treatment aims to eliminate or correct these three factors leading to deformity and impaired movement. The muscle "spasm" must be treated as soon as the diagnosis is made. A delay of as little as three or four weeks may seriously compromise the results. Treatment consists in the application of hot packs of a measured size to fit muscles without immobilizing the joints. These woolen packs are immersed in boiling water, wrung out twice through a tight wringer at the bedside, and applied quickly to the involved part. The pack is then rapidly covered with oiled silk and a layer of dry flannel. The packs are changed every fifteen minutes if "spasm" is acute—otherwise, every two hours for a twelve-hour period each day. Spasm is usually relieved within a week by such treatment, but packing is continued for weeks or months to any muscle exhibiting contracture or shortening. Although the original temperature is high, there is rather rapid cooling, and at the end of two hours there is probably a tendency for the body to heat the pack. This is in reality, then, a type of contrast therapy.

The patient is placed on a firm mattress with boards beneath and a space at the foot of the bed so that the heels do not rest on the mattress. A footboard is provided, but the feet are not allowed to touch this so long as there is any 'spasm' of the gastrocnemius muscles. Later, the feet are placed firmly against the board, with pressure, to stimulate the standing reflexes.

No active or passive movements that cause any spasm or pain are allowed. When the "spasm" is relieved, only passive motions are started while the patient is still in the packs, and the muscles are said to be 'stimulated' by such motions. One might interpret this physiologically as setting up a barrage of proprioceptive impulses to facilitate the motor pathway and proper pattern of response. Active motion or muscle re-education begins only when 'spasm' has been relieved. This may be within a week in some cases, whereas in others, residual "spasm" in some muscles may require hot packs for months.

The Kenny system of muscle treatment sizes the isolated action of muscles for each joint.

exquisite control of agonists and antagonists so that smooth rhythmical motions are obtained. There is no effort to strengthen individual muscles by resistive exercises, but strength is increased by repeated co-ordinated movements. All the patients I saw in Minneapolis were beautifully trained in the performance of these motions and were flexible to a degree rarely seen in average normal persons.

The use of the respirator has been abandoned on the theory that the difficulty in breathing is due to the painful "spasm" of the pectoral and intercostal muscles, and with proper care of the airways and relief of the "spasm" by hot fomentations, spontaneous breathing is regained. Patients who do not respond to this and have complete paralysis or bulbar paralysis are not helped by the respirator in any event. The respirator precludes the use of hot packs and tends to increase the "spasm" by stretching the painful muscles. Careful nursing is particularly needed in these cases, and packs may be necessary during all waking hours. Moving pictures have demonstrated the effective relief of such "spasm" by packs and subsequent recovery. The contrast between patients treated by respirator and those treated by the Kenny method six months later is remarkable and the best argument for the latter treatment.

The most convincing evidence available at present in favor of the theory that untreated muscle "spasm" leads to contracture deformities is a comparison of the Kenny-treated patients with others in the same epidemic treated early by immobilization without packs. Whereas in the first group there was complete freedom of motion in all joints through a normal range, in the latter, a mild or marked degree of stiffness and contracture could be demonstrated, particularly of the posterior muscles of the back and lower extremities.

The nature of this muscle "spasm" or its mechanism of production is unknown, and at present no clinical or experimental studies have been completed. One may speculate on various possibilities. There may be a direct action of the virus or a toxin on the muscles, hyperirritability of affected anterior-horn cells, hypersensitivity to acetylcholine due to denervation, acetylcholine contracture, ischemic contracture or protective reflex spasm to avoid painful motion. The clinical impression that irreversible changes may occur if the patient is untreated for three weeks warrants investigation. One type of study that is easily carried out is electromyography. The most recent patient available in our clinic is being studied by this method. The onset of this patient's poliomyelitis was four months ago, and he now has partial paralysis of one shoulder girdle and upper arm. He was treated with an airplane splint and daily physical therapy in

the usual manner. The biceps, trapezius and pectoral muscles are now slightly shortened and tense, and occasionally show involuntary fasciculation. In maximum position of relaxation, the electromyographic tracings show marked electrical activity. This was lessened by thirty minutes of diathermy, according to a later observation. Some objective evidence that there is abnormal electrical activity in a muscle with "spasm" following poliomyelitis is thus demonstrated, although the mechanism is not explained.

The apparent paralysis or "alienation" of antagonistic muscles may be due to inhibitory pain reflexes, which are well recognized by physiologists. Immobilization is known to lead to atrophy and not infrequently to temporary loss of voluntary function. There may be, in addition, some actual weakness owing to partial anterior-horn-cell destruction. This should be ascertained in the future by study of electrical excitability and action potentials.

In one old case of infantile paralysis with a foot drop and an anterior tibial muscle rated as "zero," I stimulated this muscle with a faradic current, obtaining an excellent contraction. This tends to corroborate the Kenny theory that some of the paralysis observed is not due to anterior-horn-cell destruction.

Investigations are indicated to study the effect of hot packs and other forms of therapy on the nerves, muscles and circulation and to determine the most efficient method of treatment. The ritualistic tendencies of Sister Kenny are not conducive to this important research.

The Kenny method of muscle re-education seems an excellent one. The emphasis on stimulation of proprioceptive impulses as an aid to normal co-ordinated motion and control of relaxation and contraction of antagonists is probably on sound physiologic ground and much more so than immobilization with arrest of the flow of such impulses.⁶ Further study on this point may also evolve superior methods.

Results

It is extremely difficult to evaluate statistically the results of treatment in different groups of patients with poliomyelitis because of the variability in the extent of paralysis that is to be expected. Eighty-four patients in the early stage have been treated in Minneapolis by the Kenny method. Of these, there are residual paralyses in ten lower and two upper extremities. Although all patients showed involvement of the neck, back and hamstrings, in no case has there been residual trunk involvement. The most striking feature on observation of these patients is the ease and co-ordination of movement and the remarkable suppleness.

None of the familiar contracture deformities are seen, and the condition of the skin, subcutaneous tissues, muscles and joints in the extremities with paralysis is better than that in most cases, as judged by inspection and palpation. Although no splints or supports are used while "spasm" is present, they are not objected to after the period of convalescence. No deformities are observed because of this lack of immobilization. The comfort and morale of patients under treatment are impressive.

Conclusions

The Kenny treatment of poliomyelitis is not based on any new theory concerning the disease, but is essentially symptomatic treatment. Emphasis is placed on overcoming muscle pain, tenderness, hyperirritability and contracture. This is not done by immobilization, but by intensive early application of hot packs of a specified nature. As a result of this therapy, Sister Kenny has been able to start muscle re-education within a few days or weeks. Her system of re-education employs stimulation of proprioceptive impulses and training in co-ordination of individual muscle actions. Stiff joints, muscle contractures and disuse atrophy are largely eliminated when this treatment is started within the first two weeks or, preferably, as soon as diagnosis is made.

The functional results appear to be equal or superior to those by any known method of treatment. Although residual flaccid paralysis is not eliminated, a definite therapeutic contribution has been made.

Sister Kenny's attempted physiologic explanations in general have not been accepted. Clinicians and physiologists must further study neuromuscular mechanisms in this disease to place treatment on a rational basis and to determine the optimum methods.

PERIPHERAL NERVE INJURIES AND PERIPHERAL NEURITIS

Physical therapy physicians are frequently called on to aid in the diagnosis and prognosis of nerve injuries by special electrical examinations. The electrical excitability of muscles and nerves may be determined to give information concerning the degree of nerve injury to detect early signs of regeneration. The response to galvanic and faradic stimulation is the familiar test used, and the presence of a typical so-called "reaction of degeneration," as described by Erb, indicates a severe nerve injury. It is impossible, however, to predict that actual loss of continuity has occurred by a single examination of this type. One may have to wait for long periods to allow for possible spontaneous regeneration. Any test that will reveal regen-

eration at an early date is then of clinical value. The return of motor function is the most reliable sign of recovery.⁷ Although sensory changes may appear earlier, they are sometimes misleading because of overlap of sensory distribution from adjacent nerves. Tinel's sign may often be present in cases without regeneration. It has also been shown that the return of response to faradic stimulation may follow return of voluntary function.⁸ Recently, quantitative studies of electrical excitability by use of stimulating currents of measured strength and duration have been found to be of practical value.⁹ By repeated determination of strength-duration curves in affected muscles, the presence or absence of regeneration was detected before being noted by any other test.⁹

Proper splinting is essential in the care of peripheral nerve injuries. If the nerve has been sutured and contains motor fibers, the splint should prevent tension on the suture line. The muscles supplied by the injured nerve should be protected from the pull of their antagonists, and as much free active use as possible should be allowed. Harmer¹⁰ has described excellent splints for use in injuries of the wrist and hand. Heat and massage are indicated to improve circulation and thus lessen passive congestion and fibrosis. Great care must be taken in the application of heat to an area with impaired sensation. Diathermy is contraindicated because of the danger of burns. Immersion in warm water and application of radiant heat are simple, effective methods that have the added advantage of safe use in the home, with proper instructions. In massaging denervated muscles, one should employ only gentle stroking and kneading motions, with great care not to injure the delicate vessel walls and muscle fibers. Limited passive movements avoid undue stiffness of joints. Supervised graded active exercises are the most important aids in the recovery of muscle strength.

The value of electrical stimulation of denervated muscle to lessen atrophy and hasten regeneration has not been settled either clinically or experimentally. The studies of Chor et al.¹¹ on monkeys and Molander and Steinitz¹² on dogs indicate that electrotherapy adds little of practical value. Fischer,¹³ working with rats, used more intensive stimulation and did diminish the degree of atrophy. More recently, Gutmann and Gutmann¹⁴ repeated similar experiments on rabbits and continued their study to cover the period of regeneration. They found that daily stimulation with an interrupted galvanic current for fifteen to twenty minutes resulted in no difference in the degree of atrophy during the first two weeks. Subsequently, the treated muscles atrophied less and showed better excitability with stronger contractions. Al-

though the time of return of voluntary function was not affected, the strength and weight of muscles increased with greater rapidity, and this difference could be appreciated two months after the first return was noted. Biopsies showed larger muscle fibers and better striation. The clinical impression of many physicians has been that electrical stimulation is beneficial at least in maintaining the muscles in a receptive condition to the return of nerve fibers. A critical analysis of the clinical effects of electrical stimulation seems of definite value. The technic of stimulation commonly used may not be most advantageous. Some evidence has been presented by Liebesny¹⁵ that the progressive Leduc current is the most effective stimulus.

Electrical stimulation has been used more routinely in facial-nerve paralysis than in any other peripheral-nerve disorder. This may be because people are more concerned with appearance of the face than other portions of the body. The evidence for its value is largely that of clinical impression. Principles of treatment for any flaccid paralysis apply to facial muscles. Splinting, with either adhesive tape or insulated wire, extending from the corner of the mouth to the ear prevents overstretching from pull of the opposite side and of gravity. Local heat with an infrared lamp and gentle stroking improve nutrition and muscle tone. Electrical stimulation, if used, should be obtained with either an interrupted galvanic or an alternating current, such as a faradic or sinusoidal current. The latter is preferable if the excitability of the muscles is sufficient to allow contractions; if not, the galvanic current must be used. Repeated contractions are stimulated to the point of fatigue. In cases in which the facial nerve has been more severely affected, a period of approximately three months will elapse before the first signs of regeneration are noted. In these cases, it has been observed that recovery is never complete. The regenerating nerve fibers apparently divide in such fashion that, instead of allowing individual action of different groups of muscles, the entire facial musculature tends to contract as a whole. There is also spontaneous fasciculation, and a tendency to contracture. The treatment at this stage of recovery should be directed toward muscle re-education to acquire symmetric facial movements. Measures to ensure relaxation of muscles rather than stimulation are indicated. The simple application of local heat is beneficial, as is skillfully administered, sedative, stroking massage. Heavy massage and electrical stimulation should be avoided in the presence of spasm and abnormal associated movements.

In the physical therapy of peripheral neuritis, the same principles apply as in the treat-

ment of peripheral-nerve injuries. Usually, less rigid attention is paid to immobilization with splints and other appliances in view of the fairly good prognosis ordinarily given this disease. In some cases, pain is a distressing symptom and difficult to relieve. Infrared radiation frequently gives some temporary relief. Fever therapy has been used with apparent benefit in a few severe cases.¹⁶

SPASTIC PARALYSIS

A great variety of pathologic processes may result in spastic paralysis. Hemiplegia following a cerebrovascular accident or cerebral trauma is a familiar clinical syndrome, and definite improvement in function can be expected in most cases from proper physical measures.

Traumatic, neoplastic, degenerative and infectious spinal-cord lesions may produce spastic paralysis of one or more extremities. The treatment is essentially the same in these cases as in the cerebral ones. If there is marked sensory involvement as well, some alteration in treatment is necessary. When physical therapy is first started, there may be a complete flaccid paralysis, which gradually changes to a partial spastic paresis. During the flaccid period, stimulative massage and passive exercises may improve the condition of the extremities. With the appearance of spasticity, however, stimulative massage should be avoided and only mild stroking or very gentle kneading used, since the muscles are hyperirritable and spasticity may be increased and thus lessen function. Local heat either from a radiant source or from the use of hot baths, locally or generally, is of some value in reducing spasticity. Muscle re-education is the most vital procedure. Patients must be taught how to acquire maximum relaxation of the spastic muscles and to attain co-ordinated movement. Each case varies in the degree of involvement, and exercises must be adjusted accordingly. There is a tendency for flexion contractures to occur, and the use of night splints aids in their prevention. Mild passive stretching also helps to prevent joint stiffness. To obtain synchronous motions of several extremities and in acquiring skilled movements, occupational therapy is exceptionally valuable.

The treatment of infantile cerebral palsy has been elaborated in some detail by Phelps¹⁷ and others,^{18, 19} and is not discussed here. The general principles of treatment as outlined above are employed in these cases.

ATAXIA

Sensory loss from involvement of cerebral centers or spinal-cord tracts may be the most disabling feature in some cases of hemiplegia, posterolateral

sclerosis accompanying pernicious anemia, tabes dorsalis, multiple sclerosis and Friedreich's ataxia. In these cases, attempts are made to improve co-ordinated movement by special muscle re-education. Emphasis is placed on gaining control of position of the extremities through visual pathways, since the normal proprioceptive impulses are lacking. Such exercises have been outlined in some detail by Coulter.²⁰ When there is spasticity as well as diminished sensation, the measures described for its treatment may be combined. With proper instruction and supervised practice, the patient should learn to carry on a program of home therapy to obtain the best results. In diseases with a tendency to progressive loss of function, such as Friedreich's ataxia and multiple sclerosis, elaborate expensive programs should be avoided, for such treatment cannot affect the course of the disease.

MISCELLANEOUS CONDITIONS

Patients with muscular dystrophy, myasthenia gravis, myotonia, periodic paralysis and progressive muscular atrophy are sometimes subjected to physical therapy, including electrical stimulation and exercises. There seems to be no rational basis for such measures. The only physical agents of value are rest and instruction in good body mechanics. Mild massage is probably harmless, and in some cases of progressive muscular atrophy may be of definite psychotherapeutic value and tends to improve impaired muscle circulation. Conceivably, the extent of fibrillation might be reduced by local heat and sedative stroking, with a consequent delay in injury, but no effect on the neurologic lesion can be anticipated.

Backache and pains referable to other joints are frequent complaints of patients with paralysis agitans. The local use of heat is of value in the temporary relief of these symptoms. Such a simple remedy, which may be repeated frequently in the home, may be very comforting. Since these patients tend to remain immobile in a sitting position, they are greatly handicapped by their rigidity when they attempt to move. Supervised therapeutic exercises, including rhythmical motions or the use of music, may distinctly improve muscular performance.²¹

Hydrotherapy has a recognized place in the treatment of psychiatric conditions. A new edition of Wright's²² textbook on hydrotherapy covers the subject thoroughly.

Electric-shock treatment is the newest development in physical treatment of patients with manic depressive psychoses and dementia praecox. The latest reports²³⁻²⁴ agree largely with those previously reviewed²⁷ in that the best results are obtained in depressed patients. A report on a subconvulsive reaction to electric shock in a normal subject is of interest.²⁵ The extent of brain damage that may result from this treatment is still indeterminate because of lack of available material for study.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND SIXTY-FIRST ANNIVERSARY

May 25, 26 and 27, 1942

THE one hundred and sixty-first anniversary of the Massachusetts Medical Society was observed in Boston on Monday, Tuesday and Wednesday, May 25, 26 and 27, 1942, at the Hotel Statler.

Fifteen hundred and fifty-six physicians and one hundred and twenty-three ladies were registered.

MONDAY, MAY 25

The annual golf tournament, under the chairmanship of Dr. Roy J. Heffernan, was held on Monday afternoon at the Commonwealth Country Club. There were twenty-four entries. The winners were as follows:

Low net (Burrage Bowl) — William R. Hill

Second low net — Hollis L. Albright

Third low net — Allen R. Barrow

Low gross — John J. Grinold

Second low gross — David P. Dutton

Third low gross — Roy J. Heffernan

The supervising censors met at 5:00 p.m. in the Hancock Room.

The Cotting Supper was served to 209 councilors in Parlors A, B and C at 6:00 p.m. The annual meeting of the Council was held in the Georgian Room at 7:00 p.m.

TUESDAY, MAY 26

A general clinical meeting was held in the Georgian Room in the forenoon under the co-chairmanship of Dr. Cadis Phipps and Dr. Edward J. O'Brien, Jr. The attendance varied from 250 to 600.

The one hundred and sixty-first annual meeting of the Society was held in the Georgian Room at 11:00 a.m. Dr. Ober, president of the Massachusetts Medical Society, presided. The attendance was about 650. The Annual Oration, "Some Remarks on Therapy for Anemia," was delivered at the close of the meeting by Dr. William B. Castle. During the course of the annual meeting, Dr. Ober introduced Dr. Forrest B. Ames, of Bangor, Maine, the only representative from other state societies present.

The annual luncheon was served in Parlors A, B and C to 190 fellows.

A clinical meeting was held in the Georgian Room from 2:00 to 5:00 p.m. under the co-chairmanship of Dr. George Leonard Schadt and

Dr. Ralph R. Stratton. The attendance was 600.

There was a reception and tea for the ladies in the Salle Moderne at 3:30 p.m. There were 62 ladies in attendance.

The annual dinner was held in the Georgian Room, at 7:00 p.m., with 506 in attendance. Dr. Frank R. Ober presided. Reverend Henry M. B. Ogilby pronounced the invocation. Dr. Frank H. Lahey, president of the American Medical Association, and Dr. Morris Fishbein, editor of the *Journal of the American Medical Association*, were the speakers. The Shattuck Lecture, "Medicine and Air Supremacy," was delivered immediately after the annual dinner by Dr. John F. Fulton, of New Haven, Connecticut.

The ladies' dinner was held at the Copley-Plaza at 7:30 p.m. There were 39 in attendance.

WEDNESDAY, MAY 27

There was a general clinical meeting in the Georgian Room from 9:00 a.m. to 12:00 noon under the co-chairmanship of Dr. Albert A. Horner and Dr. Edward P. Bagg.

Dr. Reginald Fitz and Dr. Frank H. Lahey discussed the Procurement and Assignment Service. Both answered many questions and emphasized the immediate need of the armed forces for doctors. They both agreed that this was not being met. They hoped that it would not be necessary to use other than voluntary means to supply this need.

The ladies held a luncheon at 1:00 p.m. at the Women's City Club of Boston. There were 49 present.

From 12:00 m. to 2:00 p.m. there was a series of section meetings and luncheons. The Section of Medicine and the Section of Surgery held a combined meeting in Parlors A, B and C under the co-chairmanship of Dr. Erwin C. Miller and Dr. Grantley W. Taylor. The attendance was 143. The Section of Pediatrics, Dr. Philip H. Sylvester, chairman, met at the Junior League, Zero Marlborough Street. The attendance was 42. The Section of Obstetrics and Gynecology met at the Women's Educational and Industrial Union, 264 Boylston Street, under the chairmanship of Dr. M. Fletcher Eades. The attendance was 70. The Section of Radiology and Physiotherapy met in Parlors D and E. Dr. Joseph H. Marks was the

chairman. The attendance was 44. The Section of Dermatology and Syphilology met in Parlor F and the Hancock Room. Dr. Arthur M. Greenwood served as chairman. The attendance was 36.

From 2:00 to 4:00 p.m. a general clinical meeting was held in the Georgian Room. Dr. Frederick J. Lynch presided. There was a symposium on minor psychiatric disturbances in war and civilian life from 4:00 to 5:00 p.m. This was the last exercise of the meeting. The attendance varied from 450 to 500.

There were 69 technical and 16 scientific exhibits. These exhibits were viewed by large numbers.

The motion pictures, as usual, attracted a large number of fellows.

The lists of admissions and deaths are appended, together with the official lists of officers, standing and special committees, councilors, censors and so forth.

MICHAEL A. TIGHE, *Secretary*

ANNUAL MEETING OF THE SOCIETY

The one hundred and sixty-first annual meeting of the Massachusetts Medical Society was called to order by the president, Dr. Frank R. Ober, in the Georgian Room, at 11:00 a.m. There were approximately 650 fellows present.

The Secretary offered the record of the last annual meeting as published in the *New England Journal of Medicine*, issue of July 3, 1941, and moved its acceptance. This motion was seconded by Dr. Arthur T. Ronan, and it was so ordered by vote of the Society.

The Secretary presented the changes in membership, as follows:

Membership of Massachusetts Medical Society, as of May 22, 1941 5652

Gains

New fellows	193
Restorations	17
	<hr/> 210

Losses

Deaths	109
Resignations	12
Deprivations	32
	<hr/> 153

Net gain 57

Membership, as of May 26, 1942 5709

The Secretary moved the acceptance of this report. This motion was seconded by Dr. William A. R. Chapin, and it was so ordered by vote of the Society.

Dr. Ober presented Dr. J. Harper Blaisdell, chairman of the Committee on By-Laws. Dr. Blaisdell moved the unanimous consent of the members present to make certain corrections in

the text as presented to each member. He explained that these corrections would in no wise affect the thought involved in the by-laws. They were offered for the purpose of improving the English and for the further purpose of making these by-laws consistent throughout. The corrections submitted by Dr. Blaisdell were as follows:

In Chapter III, Section 5, line 33, after the word "councilors" insert "elect," so as to conform with Section 6, line 13, of Chapter III.

Correct Chapter V, Section 3, beginning with line 9, to read "applicant subscribes to the by-laws of the Society and code of ethics of the Society and of the American Medical Association. . . ."

Correct Chapter V, Section 3, so that the paragraph beginning on line 13 shall read as follows: "He shall furnish each new fellow with a copy of the *Digest, By-Laws, Code of Ethics and Medical Defense Act* of the Society, and of the *Code of Ethics* of the American Medical Association."

In Chapter V, Section 3, the paragraph beginning on line 17 and ending with the word "examined," should be deleted to comply with the deletion of Section 4 in this same chapter as this section appeared in the original text.

Correct Chapter VI, Section 8, so as to read as follows: "The traveling and incidental expenses of the officers, of the committees of the Society elected by districts and of standing committees of the Society, on request, shall be paid by the Treasurer, on presentation of an itemized bill duly approved by the President."

Dr. Blaisdell's motion was seconded by Dr. George Leonard Schadt, and it was so ordered by the unanimous consent of the members.

The first four chapters of the text as submitted, with the corrections noted, were adopted by the members without dissent. The corresponding chapters of the by-laws as amended in 1941 were deleted by vote of the members without dissent.

Dr. Blaisdell moved the adoption of Chapter V of the text as submitted. This motion was seconded by Dr. William H. Allen.

Dr. Herrman L. Blumgart said he had serious misgivings in connection with Chapter V, Section 2(b). He added that the state government, through the Massachusetts Board of Registration in Medicine, decides on the professional competence of applicants, and to the Society is left the determination of the proper character of all such applicants. It seems clear, he continued, that this by-law provides for very careful supervision and screening of all applicants according to the judgment of the individual members of the committees, and by adding to all that, the requirement of practice in the United States for five years, a grave injustice will be done to certain applicants.

Dr. Joseph H. Pratt said that he was in agreement with Dr. Blumgart and that a great wrong will be done if properly qualified physicians are not permitted to join the Massachusetts Medical Society until five years have passed after they have

been accepted as qualified physicians by the Massachusetts Board of Registration in Medicine.

Dr. Oliver Cope said he thought that Section 2 (b) as it appears in the text was somewhat revolutionary in concept. He added that there were many objections to it. It indicated, he continued, that the membership committees of the district medical societies are incompetent to decide who should be taken into membership.

Dr. Robert B. Osgood expressed the thought that Section 2(b) as it appears in the text is un-American and that it is not appropriate coming at this time when we are trying to obtain unity.

Dr. Blaisdell said there was nothing revolutionary in Section 2(b) as it appears in the text. He quoted from the by-laws as amended in 1941 as follows:

An applicant for fellowship who is a graduate of a foreign medical school or college or a domestic medical school or college not on the list recognized by the Council or of a medical school no longer in existence, and who has practiced for a minimum of five years, shall apply for fellowship

He referred to Burrage's *History of the Massachusetts Medical Society* as explanatory of what was in the minds of the originators of the old by-law. He said that this history made it very clear that applicants for membership should have lived in a community sufficiently long to afford their conferees opportunity to pass on their standards of practice. He added that the supervising censors overwhelmingly supported a much more restrictive Section 2(b) than the one that appears in the text.

Dr. David L. Halbersleben wanted to know if it was possible for these men to become honorary members. He was answered in the affirmative.

Dr. George D. Henderson, a member of the Committee on Medical Education, spoke in agreement with Dr. Pratt and Dr. Blumgart.

Dr. John Fallon pointed out that if Section 2 (b) of the text was not accepted there would be a serious upset of other parts of the text as presented. He added that the Committee on By-Laws and the Council, in adopting Section 2 (b) of the text, felt it took about five years to really know what kind of medicine a fellow practiced.

Dr. Jacob Fine observed that since 1937 the Massachusetts Board of Registration in Medicine had licensed 250 graduates of foreign medical schools and of that number about 100 are now in practice in Massachusetts. He added that the number of these men who have not lived up to the professional and ethical qualifications of the Society is insignificant. He added further that these men would not be permitted to take their patients to hospitals unless they were members of the Massa-

chusetts Medical Society. The best opportunity in which to study such men would therefore be lost.

Dr. Blaisdell at this point, with the unanimous consent of the members, withdrew his motion to adopt Chapter V. He then moved to adopt Section 2 (b) of Chapter V of the text as presented. This motion was seconded by Dr. Albert A. Hornor.

At the request of Dr. Reginald Fitz, Dr. Blaisdell read Section 2 (b) of Chapter V of the text as presented. This section reads as follows:

(b) The secretary of a district society shall receive an application from a graduate of a discontinued medical school, a foreign medical school or any medical school not approved by the Council only when:

The applicant has possessed a license to practice medicine in the United States or its territories for at least five years. This license shall be verified by the district secretary and the data relating to it shall be recorded in the applicant's application blank;

The applicant has submitted with his application the name and address of a sponsor who is a fellow of the district society concerned; and

The sponsor has caused to be delivered by fellows of the Society to the secretary of the district society *confidential* written opinions on the qualifications of the applicant.

Dr. Ober, having appointed Dr. Fallon, Dr. Fitz, Dr. Allen G. Rice and Dr. Henry T. Hutchins tellers, called for a show of hands on the part of those who favored the adoption of Section 2 (b) of the text as presented. He then called for a show of hands on the part of those opposed.

He announced the vote as 198 for adoption and 147 against. He therefore declared Section 2 (b) of Chapter V as it appears in the text adopted.

Dr. Blaisdell moved the adoption of Chapter V of the text in its entirety. This motion was seconded by Dr. Charles D. McCann, and it was so ordered by vote of the members.

Dr. Blaisdell moved the deletion of Chapter V of the by-laws as amended in 1941. This motion was seconded by Dr. Peirce H. Leavitt, and it was so ordered by vote of the members.

Dr. Blaisdell moved the adoption of Chapter VI as presented in the text. This motion was seconded by Dr. Maurice Gerstein.

Dr. Chapin believed that the district treasurers should continue to collect the dues of the members of the Massachusetts Medical Society. He expressed his opposition to the chapter in the text that changed this arrangement.

Dr. Blaisdell asked for the unanimous consent of the members to withdraw his motion to adopt Chapter VI. This consent was granted.

Dr. Blaisdell moved that Section 5 of Chapter VI be adopted. This motion was seconded by a fellow. The vote which was taken by a show of hands was 191 for adoption and 40 against. Dr.

Ober announced that Section 5 of Chapter VI of the text was adopted

Dr. Blaisdell moved the adoption of Sections 1, 2, 3, 4, 6, 7 and 8 of Chapter VI of the text. This motion was seconded by Dr. Hornor, and it was so ordered by the vote of the Council

Dr. Blaisdell moved the deletion of Chapter VI of the by-laws as amended in 1941. This motion was seconded by Dr. David D. Scannell, and it was so ordered by vote of the Council

Dr. Blaisdell moved the adoption of Chapter VII of the text. This motion was seconded by Dr. Scannell

Dr. Chapin expressed a wish to hear from Dr. Schadt on the last paragraph under Section 5. Dr. Ober invited Dr. Schadt to discuss this section

Dr. Schadt directed the attention of the members to Section 5 of Chapter VII, which provides that the Committee on Nominations shall cause its report to be published in the notice of the annual meeting of the Council. He said that he was fearful that this departure from what had been the practice over the years would lead to a good deal of political campaigning. He expressed the hope that this section of the text would not be adopted

Dr. Carl Bearse believed that Section 5 of Chapter VII of the text should be adopted. He pointed out that the election of the officers of the Massachusetts Medical Society was a most important matter and that the members of the Committee on Nominations should not be hurried, as they were then, in performing their most important duty. He added that the Committee on Nominations could meet more than once and this fact would be of great help to it in arriving at a proper choice

Dr. Fallon agreed with Dr. Bearse. He added that the adoption of Section 5 of Chapter VII would bring these nominations out in the open

Chapter VII was adopted by vote of the members

Dr. Blaisdell moved the deletion of Chapter VII of the by-laws as amended in 1941. This motion was seconded by Dr. Leavitt, and it was so ordered by vote of the members

Dr. Blaisdell moved the adoption of Chapter VIII of the text as presented. This motion was seconded by Dr. Leavitt, and it was so ordered by vote of the members

Dr. Blaisdell moved that Chapter VIII of the by-laws as amended in 1941 be deleted. This motion was seconded by Dr. Chapin, and it was so ordered by vote of the members

Dr. Blaisdell moved that Chapter IX of the text be adopted. This motion was seconded by Dr. Bearse, and it was so ordered by vote of the members

Dr. Blaisdell moved that Chapter IX of the by-laws as amended in 1941 be deleted. This motion was seconded by Dr. Leavitt, and it was so ordered by vote of the members

Dr. Blaisdell moved that the by-laws as a whole, with the corrections noted, as they appear in the text before the body, be adopted. Dr. Leavitt seconded this motion, and it was so ordered by vote of the members

Dr. James C. McCann moved that the President be instructed to express to the Commissioner of Insurance and his associates the appreciation of the Massachusetts Medical Society for their kind co-operation and help in establishing Massachusetts Medical Service. This motion was seconded by Dr. Blaisdell, and it was so ordered by vote of the members

Dr. McCann offered the following resolution

WHEREAS, The House of Delegates of the American Medical Association in special session in 1935 stated that it reaffirms, also, its encouragement to local medical organizations to establish plans for the provision of adequate medical services for all the people, adjusted to present economic conditions, by voluntary budgeting,

WHEREAS, The delegates amplified this statement in special session September 16 and 17, 1938, with the restrictive remark that "in addition to insurance for hospitalization your committee believes it is practicable to develop cash indemnity insurance plans to cover, in whole or in part, the costs of emergency or prolonged illnesses",

WHEREAS, Pursuant to this obligation thus imposed upon state and county medical societies they have so acted as to warrant the report that by the summer of 1941, there were twenty state medical societies that had taken some steps toward the introduction of a medical service plan to operate over the entire state" (1941 edition *Organized Payments for Medical Services*), and since nearly the entirety of effectively organized and planned service schemes have utilized the principle of medical service contracts (California, Michigan, Buffalo, Utah, North Carolina, Washington, Oregon, Pennsylvania, New Jersey, Massachusetts and others),

WHEREAS, These major experimenting groups have not found wholly valid or practical for effectively aiding the lower income groups, such restricting and restrictive statements relative to contracts coming from the House of Delegates (1938) as "your committee unanimously concurs in the suggestion and recommendation that the American Medical Association adopt the principle that in any plan or arrangement for the provision of medical services the benefit shall be paid in cash directly to the individual member," and such statements as that from the revised publication, 1941 *Organized Payments for Medical Services*, page 21, that "the attitude of the American Medical Association towards methods of payment of medical bills has been clearly defined. The position [is plainly stated] that benefits should be paid to the patients in cash in the same manner as premiums are collected from them",

WHEREAS, The empirical findings of the major experimenting groups that a medical service contract best serves the end of a more adequate distribution of needed medical care in a manner which effectually protects the

lower income groups against the mounting costs of medical care, and is directly in accord with the realistic attitude of the Massachusetts Commissioner of Insurance that the "capital" sustaining such plans with payments on the unit basis is not cash but the physician's service; and

WHEREAS, The statement of the House of Delegates September 16 and 17, 1938, that "your committee recognizes the soundness of the principles of the workmen's compensation laws" implies acceptance of the important compensation principle of arranging the delivery of complete service to the patient without additional charge by the doctor, and with payment of the physician from insurance funds, all of which is the essence of a medical-service contract; be it therefore

RESOLVED, That the state and county units of the American Medical Association in undertaking medical-service plans at the behest of the parent organization will have their hand supported if medical-service contracts, as well as cash-indemnity contracts, are given equally frank direct approval by the House of Delegates.

Dr. McCann moved that the delegates from the Massachusetts Medical Society be instructed to present this resolution to the House of Delegates of the American Medical Association at its meeting in June in Atlantic City. This motion was seconded by Dr. Schadt, and it was so ordered by vote of the members.

Dr. Fitz presented the following resolution:

WHEREAS, During the present national emergency there is urgent need for a large number of young medical officers to be enrolled from Massachusetts in the Medical Corps of the Army; be it therefore

RESOLVED, That the Massachusetts Medical Society in annual meeting assembled, respectfully requests that physicians residing in Massachusetts who wish to volunteer their services, who are American citizens, who have spent four academic years of thirty-two weeks each in a school legally chartered to teach the practice of medicine, who have received a diploma as a doctor of medicine from such a school, who have had at least a year's internship in a registered hospital and who are licensed to practice medicine in Massachusetts, be regarded as eligible for commission in the Medical Corps of the United States Army provided that they are declared available for this distinction by the local committees of the Procurement and Assignment Service for Physicians in the areas where they have legal residence, and by the Massachusetts State Committee of the Procurement and Assignment Service for Physicians; and be it further

RESOLVED, That copies of this resolution be sent to the Secretary of War, the Surgeon General of the United States Army, Mr. Paul V. McNutt, director, Office of Defense Health and Welfare Services, Dr. Frank H. Lahey, chairman, Directing Board, and Dr. Walter G. Phippen, chairman, First Corps Area Committee.

Dr. Fitz moved the adoption of the resolution. This motion was seconded by Dr. Charles E. Mongan, and it was so ordered by vote of the members.

The designated delegates from the other New England state medical societies were as follows:

MAINE: Dr. Forrest B. Ames, Bangor

NEW HAMPSHIRE: Dr. W. J. Paul Dye, Wolfeboro
Dr. Wallis D. Walker, Rye Beach

VERMONT: Dr. Clair D. Rublee, Newport

RHODE ISLAND: Dr. Charles A. McDonald, Providence
Dr. Joseph C. O'Connell, Providence

CONNECTICUT: Dr. Joseph A. LaPalme, Putnam
Dr. William J. German, New Haven

Dr. Ober sought to introduce each of these delegates. Dr. Forrest B. Ames, Bangor, was the only one to respond.

Dr. Ames said that, as a former member of the Massachusetts Medical Society, he was particularly pleased to have the privilege of bringing the greetings of the Maine Medical Association. He commented on the references which had been made earlier in the meeting to Massachusetts Medical Service and said that there was considerable interest in this subject in Maine. He invited the members of the Massachusetts Medical Society to the annual meeting of the Maine Medical Association to be held June 21, 22 and 23 at Poland Spring.

Dr. William H. Allen was recognized by the chair. He offered the following recommendation:

The supervising censors recommend that Chapter V, Section 2(a), as it relates to the timetable which governs graduates of approved schools in their applications for membership in the Massachusetts Medical Society, be waived in the interest of those who are either in or who have applied for commissions in the armed forces of our country. The Board of Supervising Censors further recommends that this regulation shall prevail only for the present emergency.

Dr. Allen moved the adoption of this recommendation. Dr. Mongan seconded the motion.

Dr. Ober told the members that a recommendation similar to this had been made to the Council at its meeting the night before, and the motion calling for its adoption had been ruled out of order. He added that the recommendation now before the meeting had been submitted to counsel and that the latter expressed it as his opinion that it was entirely proper for the members of the Society to adopt it.

The motion to adopt the recommendation was put and adopted without dissent.

The Secretary again appealed to the district secretaries to send in the names of their fellows who have entered the armed forces of the United States.

Dr. Frank R. Ober then reported on "The State of the Society" as follows:

It is the duty of the retiring president at the end of his term of office to report on the state of the Society.

The total membership is now 5709. The net gain in membership over last year is 57.

The Council has held four sessions, three regular and one special. The attendance of councilors at these meetings showed a slight falling off from the previous year. This is to be deplored. Members of the Council are elected to represent their districts, and it is therefore the duty of each councilor, as an officer, to attend the meetings of the Council and remain until adjournment takes place.

Ten district-society meetings were attended by the president. Since we now have a president-elect whose duty may be to assist the president, it seems desirable that the president-elect be invited to make at least half of these visitations, thus relieving a part of the president's burdens and giving the president-elect a better acquaintance with the members.

Last year three fundamental changes were made in the by-laws: the office of president-elect was created, the term of president was limited to one year, and provision was made for an executive committee of the Council.

The Executive Committee held its first meeting on June 23, 1941, and proceeded to organize. Dr. Walter G. Phippen, your last president, was invited to be present, since it was through his efforts that this committee was advocated. Dr. Phippen was asked to speak, and he outlined some of the possible functions and duties of this new committee. The new by-laws provided that an executive secretary might be elected by the Executive Committee. It was decided to elect the executive secretary at this meeting. In order that this committee might be kept active, it was voted that it could make decisions in emergencies, advise with the officers of the Society, discuss and approve *ad interim* appointments, and formulate matters of policy in the affairs of the Society before presentation to the Council. The Executive Committee also voted that all committees having important reports to make before the Council should first submit them to the Executive Committee for review and discussion. The discussion of the committee is then to be presented to the Council in a formal report, with the idea that its deliberations might be expedited.

The Executive Committee has held three regular meetings and five special meetings. The special meetings were called to consider matters of great importance to the Society as a whole. Two meetings were held for the purpose of discussing the proposed new by-laws; one for electing the board of directors of the Massachusetts Medical Service; and one to hear and discuss the report of the chairman of the Massachusetts Committee of the Procurement and Assignment Service.

The Society is particularly fortunate that the Council elected last year a secretary who is ideal for the job. Dr. Tighe has devoted a great deal of time to the performance of his duties. His records are kept as they should be; his counsel is wise; his devotion to the best interests of the Society cannot be surpassed; in fact, it would seem to one who has worked so closely with him that his main interest in life is what is best for the Society. We should congratulate ourselves that we have selected wisely and well in filling this important office. To him, I extend the heartfelt thanks of the Society.

Your able treasurer reports that the finances of the Society are in as excellent a condition as these precarious times will permit. The Society has received interest on all securities held (except as in 1940). There are difficulties in investing funds in safe securities except those of too long maturation and at too high prices. Short

first-class bonds are in demand at low returns but are safe. The collection of annual dues is not so well maintained as in 1940. There have been more requests for remission of dues than in the preceding year, in large part owing to the fact that an increasing number of our members are going into the armed services. The expenses of the Society from January 1 to May 1 have increased, owing in part to increased activities of the Society and in part to legal services. The Society is indeed fortunate that it has a treasurer who is so unselfishly devoted to our best interests. I thank him also for his support and wisdom in the able management of our financial affairs.

The standing committees have performed their duties efficiently and most satisfactorily.

The Committee on Ethics and Discipline is to be congratulated on its circumspect attitude and method of procedure dealing with those problems which come before it. Your president has attended nearly all the sessions and feels well repaid for the time spent and knowledge gained.

The Committee on State and National Legislation has not had much to do since the last annual meeting because the General Court did not meet this year. It is quite obvious that this committee has long been accustomed to limit a large part of its activities to the deliberations of the State Legislature. This should not be, because there are many problems that are being brought before Congress almost daily, a proper knowledge of which is often of the utmost concern to all of us.

The new by-laws provide for a new Committee on Legislation, whose duty should be to gather information about all matters of legislation, both state and national, in order that the Society may be apprised in due time, so that measures may be taken to support what seems to be good and to oppose when such matters do not seem best in the interest of the public welfare.

The Committee on Public Relations is one of the most important and most useful in the Society. It has been extremely useful in ironing out the plan for the Massachusetts Medical Service, before this plan was presented to the Council. Dr. Thomas H. Lanman resigned as chairman of the subcommittee that had charge of working out the details of the insurance corporation. Dr. James C. McCann was appointed to succeed him. This committee, under the able leadership of Dr. McCann, has done a superb piece of work in organizing the insurance plan for low-income groups. This plan was presented in full to the Executive Committee of the Council for consideration and review, and then was finally whipped into its present shape and accepted by the Council. The corporation, which consists of the members of the Executive Committee, elected the board of directors on May 6, and also the clerk, Mr. Edmund L. Twomey, who ably guided the subcommittee throughout the formative stages. I wish to express my deep appreciation in behalf of the Society to all those whose untiring efforts made the plan possible.

The Committee on Postgraduate Instruction conducted a very successful assembly in October, 1941. The attendance was much larger than in the two preceding years, and there was no financial loss. There was some curtailment of the extension courses, owing to the fact that there was no federal aid for the general courses.

The *New England Journal of Medicine* continues to maintain its high standards and growth. There has been an increase of 775 subscriptions to nonmembers of the Society. Sixty per cent of the papers presented to the

editorial board were accepted. The operating loss this year was \$16,513.78 (nearly \$4000 less than in the previous year), and is covered by your contribution to the *Journal* of \$17,400.

The Society is taking an active part in the war program. The Committee on Preparedness was set up, which has thoroughly studied, together with subcommittees in the district societies, the situation of the physicians in the Commonwealth with regard to civil and hospital needs and their availability for induction into the armed services of the country. The need for medical officers is very pressing owing to the rapid expansion of the Army and Navy. We all must be prepared to make great sacrifices if the United Nations are to win this most terrible war of all time.

A Committee on Rehabilitation was appointed. The object of this committee is to see that those draftees having remediable defects may be rehabilitated so that they will be fit for war service. The committee is functioning in conjunction with the selective-service authorities.

At the October meeting of the Council, it was voted that a committee be appointed to revise the by-laws of the Society. Such a committee was organized and began to function almost immediately. Frequent meetings were held by the committee. Your president and secretary attended practically all of these. Many hours were spent every week in the study and revision of the by-laws. The new by-laws were adopted at a special meeting of the Council held in April. The attendance at this meeting was 189. Every old by-law was considered thoroughly. The continuity was rearranged so that in the new by-laws there would be eliminated the necessity of searching through many pages for special by-laws, which obviously should be in one place. There was added a new standing committee, the Committee on Industrial Medicine. The Committee on Legislation was changed to an elected committee. All elected committees were grouped and put in a prominent place. Important changes in composition without changes in principle were also made. The set-up of the Committee on Membership was changed so that it would decide about membership in the Society. I wish to thank the Committee on By-Laws for its devotion to duty in producing your new by-laws.

Last year President Phippen suggested that it was time to think about changes in the headquarters of the Society. It is obvious that these quarters are inadequate for the conduct of the affairs of the Society. However, no move should be made by the Massachusetts Medical Society which would separate by any great distance the location of the Boston Medical Library from that of the headquarters, owing to the facts that the office of the *New England Journal of Medicine* is in the headquarters of the Society and that the facilities of the Boston Medical Library should be at the disposal of the *Journal*.

Dr. David Cheever, president of the Boston Medical Library, published a report in the April 30 number of the *Journal* showing the present condition of the library. The library had an investigation made by competent authorities on medical-library matters. This report shows that the library is now centrally located and has sufficient storage space for many years to come, but is understaffed because of lack of funds. It is my recommendation that some organized effort be made to help solve this situation.

The activities of the Massachusetts Medical Society are expanding more and more every year. It is necessary to support these activities by having committees chosen wisely. The officers of the Society are finding that more and more demands are being made on their time in order to manage its affairs properly.

I have endeavored at all times to work for the best interests of the Society as a whole to the end that every physician in the Commonwealth will realize more and more that he can depend on an organization which he can support and which will support him in his efforts to care for and guard the health of his patients.

May I now thank all those officers and committees who have performed their duties so faithfully and well. I also wish to express my heartfelt appreciation for the confidence that you, the members of the Massachusetts Medical Society, have placed in me during the past year.

Dr. Ober introduced Dr. William B. Castle, who delivered the Annual Oration, entitled, "Some Remarks on Therapy for Anemia" (published in the *New England Journal of Medicine*, issue of June 4, 1942).

Dr. Ober announced that the Council would reconvene at 2:45 p. m. in the Salle Moderne.

Dr. Mongan moved that a rising vote of thanks be extended to Dr. O'Halloran and his associates on the Committee of Arrangements for the fine program they had presented. This motion was seconded by Dr. Bearse and adopted unanimously in the midst of great applause.

Dr. Mongan moved a rising vote of thanks to Dr. Castle. This motion was seconded by Dr. Fallon and adopted with great applause.

Dr. Mongan commented on the importance of the work that had been accomplished in the year that had just come to a close. He called it a history-making year. He complimented the executive officers of the Society and moved that the members extend to them a rising vote of thanks. This motion was seconded and adopted with loud applause.

Dr. Ober called on Dr. Roger I. Lee, president-elect of the Society. Dr. Lee was not present.

Dr. Ober presented Dr. George Leonard Schadt, president of the Massachusetts Medical Society for the ensuing year. Dr. Schadt was greeted with great applause.

It was moved by Dr. Mongan and seconded by Dr. Fitz that the meeting be adjourned. The motion was adopted by vote of the members.

At 1:55 p. m. Dr. Ober declared the one hundred and sixty-first annual meeting of the Society adjourned.

MICHAEL A. TIGHE, *Secretary*

APPENDIX

ADMISSIONS RECORDED FROM MAY 22, 1941, TO MAY 26, 1942

YEAR OF ADMISSION	NAME AND RESIDENCE	MEDICAL SCHOOL
1942	Adams, Raymond Delaney, Winchester	Duke
1941	*Adler, Eric David, Greenfield	University of Heidelberg
1941	Allen, Fred Harold, Jr., Boston	Harvard
1942	*Andosca, John Baptist, Mattapan	Royal College of Physicians and Surgeons London
1942	*Angyal, Andras, Worcester	University of Turin
1942	Ashley, Alva, Needham	Vanderbilt
1942	Bailey, Charles Cabell, Boston	University of Virginia
1942	*Brone, William Daniel, Winchester	Middlesex
1941	Barry, Thomas A., East Boston	Tufts
1941	Bedinger, Ada Doughty, Taunton	University of Pennsylvania
1941	*Bell, Solomon Z., Dorchester	Middlesex
1941	Belsky, John, Chelsea	Boston University
1942	Benedetti, Charles Carl, Hathorne	Hahnemann
1941	*Bennett, Nathaniel Noah, Brookline	Middlesex
1942	Bergin, Joseph David, Worcester	Boston University
1941	*Bernstein, Siegmund, New Bedford	University of Vienna
1942	*Bialow, Solomon Philip, Newton Centre	Middlesex
1942	Blanchard, Stanley W., Boston	Tufts
1942	*Bloomenthal, Abraham Phillip, Waltham	Middlesex
1942	Bloomfield, Stanley T., Boston	Boston University
1941	*Blumenthal, Fred Ralph, Taunton	University of Berlin
1942	*Borenstein, Morris Victor, Springfield	University of Vienna
1941	*Boynton, George Hollis, Billerica	Middlesex
1942	Branch, Dexter Roland, Lynn	New York University
1941	*Brick, Edward Jerome, Northampton	Middlesex
1942	Briere, Arnold Charles, Lynn	Tufts
1941	Broadhurst, Alice Mary, Watertown	Tufts
1942	Broady, Harold, Lowell	St. Louis University
1942	Brownlee, Robert Emery, Boston	Harvard
1942	*Buono, Charles Louis, Worcester	Middlesex
1942	Burke, Jacob B., Chelsea	Tufts
1942	Burke, John Edward, Cambridge	Tufts
1941	Carpenter, Frederick John, Pittsfield	McGill
1942	Cartier, Roland Rodolphe, Rutland	University of Montreal
1941	Casey, David Timothy, Cambridge	Tufts
1942	Chadwell, Virginia Towse, Swampscott	Boston University
1942	Chase, John Seaman, Brockton	Harvard
1942	*Chase, Louis Samuel, Cambridge	University of Berlin
1941	*Cohn, Ernst, Dorchester	University of Wuerzburg
1941	Crosby, Walter Franklin, Sterling	Tufts
1941	Cutter, Edward Parker, Cambridge	Harvard
1942	*Denny Brown, Derek Ernest, Cambridge	Osigo University
1941	*Deutsch, Felix, Cambridge	University of Vienna
1942	Dexter, Lewis, Boston	Harvard
1942	*DiSalvo, Joseph John, Lawrence	Middlesex
1942	*Dobelle, Martin, Pittsfield	University of Ghent
1942	*Douglass, Hector Bertram, Bridgewater	Middlesex
1942	Durfee, Marion Birch, Worcester	University of Colorado
1941	Eigner, Sidney, Lynn	Boston University
1942	Ernst, Robert Goodfellow, Springfield	Yale
1942	Evans, Frances Eugenia, Boston	Tulane University of Louisiana
1942	Fairbanks, Edward Joseph, Webster	Harvard
1942	*Felsen, Hermann, Easthampton	Anderson College of Medicine, Glasgow
1942	Ferguson, Albert Barnett, Canton	Cornell
1942	*Finkelstein, Samuel Manuel, Dorchester	Middlesex
1941	Fiumara, Nicholas John, Boston	Boston University
1942	Flynn, Simon A., Boston	McGill
1941	Foot, Estelle, Waverley	University of Vermont
1942	Forster, Francis Michael, Wellesley	" " Cincinnati
1941	*Forti, Emilio, Chestnut Hill	of Modena
1941	† Freund, Ernest, Boston	ague
1942	Galuszka, Bronislaw Andrew, Barre	Tufts

1941	*Gerbi, Claudio, Boston	Royal University of Milan, Italy

**CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITAL**ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, MD, *Editor***CASE 28281****PRESENTATION OF CASE**

A fifteen-year-old schoolboy was admitted to the hospital because of weakness following an illness characterized by jaundice and skin eruption.

The patient was well until a year before entry, when there was insidious onset of slight jaundice, accompanied by and possibly slightly preceded by lack of energy. The stools and urine both appeared light yellow. The patient was advised by his physician to take a dose of "salts" nightly. Subsequently, hemorrhoids developed and required lancing. However, the jaundice persisted, and was accompanied by yellow urine and stools, moderate anorexia and lassitude. Nine months before entry, blisters filled with yellowish, watery fluid appeared on the front of the chest. His physician prescribed a paste and a lotion, which somewhat allayed the itching. The lesions spread to the posterior surfaces of the legs and thighs. A dermatologist prescribed vitamin D and sodium cacodylate. The latter drug was given intramuscularly in 3 gr. doses, daily at first and later every other day. The blisters "turned purple" and then dried up. In a month, the patient's skin was clear. Therapy was discontinued, and in ten days the entire surface of the back and the inner aspects of the thighs were involved by a severe recurrence. The blisters were as large as "bunches of grapes." Cacodylate therapy was reinstituted, with improvement as dramatic as before. Throughout the nine months preceding entry, the patient's slight jaundice remained unaltered. There was some improvement in appetite. The colors of the urines and stools tended to fluctuate, with an inverse relation, one becoming lighter as the other darkened. Two weeks before entry, the patient developed a sore throat, with swelling of the lymph nodes in the right side of the neck, fever and darkening of the urine. There was also some swelling of the abdomen. Fifteen pounds' weight was lost in the first six months of the illness, and regained in the last six months.

The past and family histories were essentially irrelevant. A maternal aunt had hives. There was no known exposure to fumes or gases, and no drugs were taken other than those prescribed in the course of the illness. Tetanus antiserum

was given to the patient three years before entry, when a firecracker exploded in his hand.

On admission, the patient appeared well developed and nourished. There was marked icterus of the scleras and of the warm, dry skin. The mouth and throat were dry and injected, with ragged, badly infected tonsils. Several teeth were carious. The posterior auricular and cervical lymph nodes were slightly enlarged, as were the nodes in the axillas and groins. The heart was of normal size, but seemed pushed upward. There was a soft apical systolic murmur. The lungs were clear. The abdomen was slightly distended, with bulging in the flanks and shifting dullness, although a fluid wave could not be elicited. The spleen was considerably enlarged, although not easily palpable. The liver seemed of normal size.

The blood pressure was 136 systolic, 76 diastolic. The temperature was 103°F, the pulse 100, and the respirations 22.

Examination of the blood showed a red cell count of 3,710,000 with 10 gm hemoglobin, and a white cell count of 4700 with 47 per cent polymorphonuclears (including 13 per cent band forms), 36 per cent large lymphocytes, 9 per cent small lymphocytes, 7 per cent monocytes and 1 per cent eosinophils. The hematocrit was 35 per cent. There were 15 per cent reticulocytes. The prothrombin time was prolonged to about twice normal. There was no increase in red cell fragility. The van den Bergh reaction was biphasic, at 90 mg per 100 cc. The serum albumin was 2.13 gm, and the globulin 4.99 gm per 100 cc. The nonprotein nitrogen was normal, with a reduction in urea nitrogen. The formal gel test was positive. Agglutination tests for heterophil antigen were negative. Four blood cultures were negative. The urine showed a + test for albumin, a trace of sugar and a ++ test for bile pigment, and was urobilinogen positive in a dilution of 1:20. The stools were gelatinous and yellow, with a negative guaiac reaction, culture was negative for pathogenic organisms.

A roentgenogram of the chest showed elevation of the diaphragm, with the heart in transverse position and small areas of atelectasis in the lungs. A roentgenogram of the abdomen showed considerable density from free fluid. The spleen seemed enlarged, with the liver slightly smaller than usual.

The temperature spiked irregularly between 100 and 105°F for two weeks, then leveled off at 100°F. The patient grew progressively worse, and there was a slight increase in ascites. Abdominal paracentesis on the seventeenth hospital day gave 7000 cc of clear, yellow, sterile fluid, with a specific gravity of 1.018, there were 80 to 100 red cells per cubic millimeter and occasional white cells in

the sediment. Treatment included only transfusions, clyses and vitamins. After four weeks, there was bleeding from the mouth and the rectum; muscular wasting was most marked in the hands, forearms and legs. Terminally, the patient became stuporous, and the temperature rose to 106°F. Death occurred on the thirty-ninth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. THOMAS V. URMY: The story is that of a prolonged mild jaundice, a rather unusual recurrent skin eruption of many months' duration and a terminal phase beginning with an acute infection of the throat and characterized by rapidly developing hepatic insufficiency.

First of all, I must say that I can think of no one diagnosis that will explain the entire picture. So far as the chronic jaundice is concerned, we can eliminate hemolytic icterus because dark urine and light stools were present from the beginning, and also because later, when the patient was studied, the red-cell fragility and the urobilinogen were normal. Furthermore, many other tests indicated a biliary-tract lesion. I think that we can assume that this patient had primary intrahepatic disease, for it does not seem likely that the low-grade jaundice that he had originally could have been due to any form of obstruction. In further differentiation, catarrhal jaundice should be considered, but apparently he had none of the fever, nausea and vomiting that usually precede the onset of jaundice. It is, of course, unusual in such a case to have continued jaundice for over a year, although occasionally this occurs. I think we can dismiss catarrhal jaundice. Since the patient was a young boy developing chronic jaundice insidiously, we should consider Hanot's cirrhosis; however, we have no account of a large liver. It is stated that when he came into the hospital the liver was not definitely felt or enlarged by x-ray. However, the words of the case record, "the liver seemed of normal size," arouse some suspicion that the physical examination may not have agreed with later findings. Furthermore, to make a diagnosis of Hanot's cirrhosis, the liver need not have been enlarged when the patient came into the hospital because he had been failing fairly rapidly for two weeks before, and the liver might well have atrophied during that time. I should also mention that a toxic jaundice from some unknown cause might have started insidiously without prodromal symptoms and might have gone on to this terminal picture, but such a diagnosis is somewhat less attractive to me than Hanot's cirrhosis.

So far as the skin lesions are concerned, I can only make a guess. The fact that they were vesicu-

lar and bullous makes me think of pemphigus and dermatitis herpetiformis.

DR. TRACY B. MALLORY: The diagnosis of the dermatologist was dermatitis herpetiformis.

DR. URMY: That was also my diagnosis, mainly because the eruption was recurrent and itched badly, which I think pemphigus usually does not do. There were no mouth lesions or lesions on the hands, as one would expect in erythema multiforme. The interesting feature of this part of the history is that the patient was given arsenic. I wonder if the arsenic could have had a toxic effect on the liver.

Several other findings mentioned in the history should be considered, although they do not change my diagnosis. Attention is called to the fact that the posterior auricular lymph nodes were palpable, as well as nodes in the groins and axillas. The clinicians were apparently impressed by them, for they did a heterophil reaction to rule out infectious mononucleosis. Certainly, the appearance of the throat and at least the differential count, if not the total white-cell count, suggest it somewhat. Also, the presence of enlarged lymph nodes and an enlarged spleen raises the question of lymphoblastoma, but I cannot explain the whole picture on that basis. I shall regard the enlarged lymph nodes as incidental.

Finally, attention is called to the wasting that took place in the terminal stages of the disease, especially of the hands, forearms and legs. I wonder if we are being told of some type of peripheral neuritis or other local disease of the arms and legs in some way connected with the general picture. I think that we cannot assume peripheral neuritis without a history of pain. It seems wisest not to read any special meaning into this description. The patient may have had a very large abdomen, so that his general emaciation was more striking in the extremities.

When he was admitted, he was running a fever. He had a sore throat and had developed ascites. The liver may have been shrunken. What evidence we have indicates that. There was a moderate anemia, a low white-cell count, as we frequently see in intrahepatic disease, and many other indications of a diseased liver, such as a prolonged prothrombin time, an elevated van den Bergh reaction, a reversal of the albumin-globulin ratio, with marked reduction of the serum albumin, and a positive formol-gel test. Finally, the abdomen was tapped, and a fluid somewhat high in specific gravity but perfectly consistent with a transudate obtained.

It is impossible to make any more definite diagnosis than chronic liver disease. I shall call it Hanot's cirrhosis perhaps only because I have

never made the diagnosis before, and I should like to. I believe that there developed terminally an acute or subacute yellow atrophy secondary to acute tonsillitis and perhaps to the arsenic therapy.

DR. WYMAN RICHARDSON: I think this might be mycosis fungoides. Since one could say that all these symptoms might be associated with it, particularly in connection with the lymph nodes, I believe that one should consider more strongly the lymphocytic type of lymphoma as a possible explanation for the whole picture.

DR. URMY: I do not know much about it, but my impression is that this sort of skin picture does not occur in mycosis fungoides and is not so amenable to this type of treatment.

DR. RICHARDSON: Sodium cacodylate was formerly given for mycosis fungoides, with temporary improvement at least.

DR. MALLORY: That would be extremely unusual at this age.

DR. RICHARDSON: That is right. That would probably rule it out.

CLINICAL DIAGNOSIS

Hepatitis, nature undetermined, with terminal liver failure.

DR. URMY'S DIAGNOSES

Hanot's cirrhosis.

Acute yellow atrophy of liver.

Dermatitis herpetiformis.

ANATOMICAL DIAGNOSES

Cirrhosis of liver, healed atrophy (toxic) type.

Splenomegaly.

Ascites.

Icterus.

Pulmonary congestion and collapse, right lower lobe.

PATHOLOGICAL DISCUSSION

DR. MALLORY: I thought in reading this history over that the dermatologist had been courageous to treat a skin rash in a jaundiced patient with arsenic, and yet on each occasion the skin rash promptly disappeared, and the jaundice did not increase. The general condition was improved rather than otherwise so that I think the dermatologist was probably justified.

Autopsy showed a liver of normal, or slightly increased, size—weighing 1700 gm., very coarsely nodular, with big masses of young liver cells and large intervening areas of scar tissue containing innumerable bile ducts, the picture that we generally consider typical of the healed stage of acute atrophy. The microscopic examination added essentially no further information. There was no evidence of fresh or recent hepatitis. The acute

episode must have been some time long past. The spleen was very much enlarged, weighing 700 gm. Certainly, it should have been easily palpable. It showed rather marked fibrosis of the type seen in long-standing portal hypertension, whatever the etiology. The kidneys were large, weighing 500 gm., were moderately bile stained, and showed pouting of the substance over the capsule, and the moderate degree of tubular degeneration that is called "bile nephrosis." I assume that it was merely secondary to the long-standing secretion of bile salts in the urine. There was nothing else.

DR. RICHARDSON: Were there any lymph nodes around the abdomen or thoracic cage?

DR. MALLORY: None that were noticed as being unusual in size.

DR. URMY: Would you guess how long it was since the atrophy had occurred?

DR. MALLORY: A year at least—perhaps much longer.

DR. URMY: Why did the patient die at this time?

DR. MALLORY: I think he unquestionably died of liver insufficiency, in spite of the size of the liver. It was a liver incapable of normal function. I am afraid that it is beyond the realms of morphologic pathology to explain why.

DR. URMY: Did the lesions suggest that the patient had improved?

DR. MALLORY: There was no active progressive hepatic-cell degeneration, but immense amounts of scar tissue had formed, some of which may have caused intrahepatic obstruction of the bile ducts or portal radicles, and the extensive reconstruction may have made the vascular architecture of the liver inadequate.

A PHYSICIAN: Do you recognize any pathologic picture that goes with dermatitis herpetiformis? What is the usual outlook in this condition?

DR. MALLORY: I am afraid I cannot answer that.

A PHYSICIAN: The condition is very difficult to treat. It is a chronic disease that usually ends fatally with some terminal infection, just like pemphigus. It is difficult to separate the two.

DR. MALLORY: I do not know of any typical post-mortem picture.

CASE 28282

PRESENTATION OF CASE

A fifty-five-year-old bartender was admitted to the hospital because of recurrent spitting of blood.

The patient was in excellent health until a year before entry, when he had a ten-day illness characterized by malaise, anorexia, coryza, dry cough, shaking chills and, probably, fever; he had no chest pain or sputum. Recovery was complete except for persistence of the dry cough. Six months before

entry, the intensity of this cough increased, during the course of a coryza, and the patient began to spit up small lumps of blood mixed with a little mucus. This continued. At first, this sputum was foul tasting, but after a week it was no longer so. Not over one or two tablespoonfuls of sputum was brought up in the course of a day, and sometimes no blood was seen for several days. In the first two weeks of this phase of the illness, there was anorexia, and a loss of 5 or 6 pounds in weight, which was subsequently regained. There were no pains, chills or fever at this time. Two months before entry, the patient consulted his physician. He was told that a roentgenogram showed "a little growth in a bronchus" and was referred to the hospital.

The patient's son had died of meningeal and renal tuberculosis. The family and past histories were otherwise of no interest. No recent dental work had been done.

On admission, the patient appeared slightly obese. The heart was slightly enlarged toward the left. The lungs were normal. The liver edge lay two fingerbreadths below the costal margin. The abdomen was otherwise normal. Bilateral indirect inguinal hernias were present. Rectal examination was negative. The fingers were not clubbed, and the legs were not tender.

The blood pressure was 130 systolic, 90 diastolic. The temperature was 99°F., the pulse 80, and the respirations 20.

Examination of the blood showed a red-cell count of 5,110,000 with 14 gm. hemoglobin, and a white-cell count of 7900 with 76 per cent polymorphonuclears, 14 per cent lymphocytes and 9 per cent monocytes. The blood Hinton reaction was negative. The urine was normal. The sputum showed no acid-fast bacilli in three examinations, but grew alpha-hemolytic streptococci in three cultures. A tuberculin test in a dilution of 1:20,000 was positive.

Roentgenograms of the chest showed a round area of consolidation, 5 cm. in diameter, in the apex of the left lower lobe, which contained a cavity without a fluid level. The left hilum was slightly lower than usual, and included a small area of calcification. The diaphragm showed normal motion. In comparison with the film taken two months before entry, the process in the apex of the left lower lobe seemed slightly decreased in size.

The temperature fluctuated from 98.6 to 100.0°F. daily. On the fifth hospital day, bronchoscopy was performed. The larynx, trachea, right bronchial tree, left main bronchus and left-upper-lobe orifice appeared normal. There was considerable blood in the trachea and left main bronchus, which

apparently came from the dorsal branch of the left lower bronchus. The distal margin of this orifice appeared slightly roughened and irregular. A biopsy obtained from this area showed chronic inflammation. The terminal branches of the left main bronchus appeared normal.

The patient was given a three-day course of sulfathiazole and attained a blood level of 5.5 mg. per 100 cc. Because of nausea, sulfadiazine was substituted, and a blood level of 11 mg. per 100 cc. was reached. He continued to raise a little blood-streaked sputum. On the seventh day of sulfadiazine medication, there was a sudden rise in temperature to 105°F., accompanied by a chill and by the appearance of a faint macular rash. The chest remained clear. Drug therapy was discontinued, and the temperature returned to its previous level in a few days. A roentgenogram taken three days before this reaction showed sharper delimitation of the shadow in the left lower lobe, with a definite fluid-free cavity included in it.

On the thirty-second hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. DONALD S. KING: To summarize briefly, the patient gave a history of infection of a year's duration, with chills, with a dry cough for six months and without fever. He then began to raise blood and continued to cough up blood and blood-streaked sputum for another six months, and had a little fever toward the end. He appears to have had some expectoration other than blood, and it is reported that it tasted badly; however, since we did not have the opportunity to smell the sputum, we cannot be sure that it was foul. We can assume that a note would have been made if it had been notably foul when the patient was in the hospital. The physical examination was remarkable because it did not show much of anything. The general condition was good,—somewhat against cancer,—and the lungs were normal; that is certainly not what we should expect in this case. There were no signs of consolidation, no diminished breath sounds, no moist rales and no musical rales. Outside the lungs, there were no palpable lymph nodes, no clubbed fingers and no source of emboli. We are left practically stranded on physical findings.

The laboratory findings help not at all except for three cultures that showed alpha-hemolytic streptococci. That may be of significance, although I should have been much more influenced by the demonstration of streptococci in smears of the sputum than in these cultures.

I shall now take up the x-ray films. I am not

so impressed with the "round tumor" as I had expected to be from reading the record.

DR AUBREY O. HAMPTON: In this film, the lesion looks like a fairly round mass. I agree that the shadows in the other films do not look at all spherical. The cavity is not very plain. It is very small and irregular. The wall of the cavity is quite thick and irregular on the inside. This triangle is the only suggestion of bronchial occlusion. I believe it indicates pleural involvement. Otherwise, there is nothing in the lung to suggest a bronchial occlusion. The bones are normal.

DR KING: This is the film at expiration, corresponding to this one at inspiration?

DR HAMPTON: Yes; it does not show any air trapping or mediastinal shift.

DR KING: Did the mass really decrease in size?

DR HAMPTON: There was a reduction of 2 cm in the diameter in the two month interval.

DR KING: This x-ray picture is not typical of anything.

Three things should be borne in mind, — cancer, tuberculosis and abscess, — and perhaps some other conditions, but these primarily. This case is not typical of cancer in my opinion. There was not the density of tumor or the sharply defined margin that one might expect. It is hard for me to accept the diagnosis of cancer. Furthermore, there is no evidence of bronchial obstruction that I can see anywhere except possibly the area that Dr Hampton pointed out, which could be infiltration and not atelectasis. I am therefore inclined to throw out cancer but should not be at all surprised if the patient had it. I cannot, however, make the diagnosis. The x-ray film does not look like it. The story is possible for it.

This case is also not typical of tuberculosis. There was not the mottling of ordinary tuberculosis, and there was no suggestion of a tuberculoma that was breaking down in the center. The most certain thing about tuberculosis is its uncertainty, and this may have been some form of tuberculosis after all. One point against tuberculosis is that, with a six months' story of hemoptysis and x-ray observation for two months, the patient should have had a more typical cavity in the lung. It is my belief that it was not tuberculosis. The negative sputum does not rule out tuberculosis, in spite of the fact that the patient was raising sputum and should have shown organisms.

One has to think about abscess, of course, because of the mention of the foul taste of the sputum. There was no putrid abscess. To make it abscess, one must make it apurid, on a streptococcal basis. We have one case that came to au-

topsy with a lesion much like this from which the pyocyanus bacillus was recovered in pure culture. If one pays a great deal of attention to sputum cultures, streptococcus is a perfectly good bet. The nearest case in our series to this, as I see it, is one of a patient who was operated on for tumor, and the lesion proved to be a streptococcal abscess. The patient in the case under discussion also started with bloody sputum and was still coughing blood at the end of three months. I think a streptococcal process might carry on this way longer than tuberculosis, so that of the three main possibilities at the moment, I should vote for streptococcal abscess.

Another vague possibility is bronchiectasis. Dr. Hampton at one time claimed to be able to see dilated bronchi on the plain film.

DR HAMPTON: I do not see any.

DR KING: The location is unusual for bronchiectasis, and if one counts this as cavity in the middle of the lobe, one must assume involvement of the parenchymatous tissue as well as bronchiectasis. There might have been some bronchiectasis associated with the process, but it was not primary bronchiectasis. Other unusual infections suggested are blastomycosis and actinomycosis. There were no skin lesions and no chest-wall sinuses to go with such diagnoses, hence, there is no reason to think of them. Then, we have our old friend, lymphoma, which we shall think about and pass over. From the x-ray standpoint, we have seen the same picture, but the story is not like it, and I am willing to throw it out. Therefore, I should say that the chances are that this was a streptococcal abscess. I shall, with some disquietude, throw out cancer and tuberculosis.

The operation interests me. I assume that a lobectomy and not a drainage was performed.

DR PAUL D. WHITE: I was visiting on the service when this man was being studied. The interesting point at that time was that in the beginning everyone, including the members of the Thoracic Clinic, guessed that the patient had a tumor of the lung. For example, Dr. Victor Balboni, on admitting the patient, believed that this was a bronchial tumor, probably adenoma, both by story and by x-ray.

DR KING: I should like to mention adenoma. I meant to put it in the differential diagnosis. The persistent bleeding is consistent. There was no bronchial obstruction, however. If an adenoma had caused this bleeding there ought to have been atelectasis, and I therefore discard adenoma.

DR WHITE: The first statement from the Thoracic Clinic was as follows: "We favor cancer as being more probable than a benign tumor. The

chances are that the growth may be beyond the reach of the bronchoscope. In either event, with or without positive biopsy, benign or malignant, exploration should be considered." As x-ray evidence developed, there was a shift of diagnosis by the members of the clinic to infection rather than tumor, and that, I think, was the status at the time of exploration. The fever, however, which was one of the features that developed, might, we thought, be explained by drug reaction.

DR. LOWREY F. DAVENPORT: We went all around the clock in the Thoracic Clinic, and when the case came to operation, the consensus was infection or tumor and, if tumor, either benign or malignant. At any rate, we took out the lobe.

DR. HAMPTON: Did you not rule out tumor on the basis of the reduction in size of the mass?

DR. DAVENPORT: As I said, we went around the clock, first favoring malignant tumor and then, following subsequent x-ray studies, abscess. We eventually decided to operate.

DR. JACOB LERMAN: It seems to me that as the mass reduced in size it became sharper. Could it not have been tumor, with secondary infection and obstruction?

CLINICAL DIAGNOSIS

Carcinoma of lung?

DR. KING'S DIAGNOSIS

Streptococcal abscess of lung.

ANATOMICAL DIAGNOSIS

Epidermoid carcinoma, bronchiogenic, left lower lobe.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: As Dr. King predicted, a lobectomy was decided on in this case, whatever the diagnosis might turn out to be. That was carried out by Dr. E. D. Churchill, and in the resected specimen we found a well-circumscribed epidermoid carcinoma, with a central cavity, 1.5 cm. in diameter, evidently the result of breakdown of the tumor tissue. All the walls of the cavity consisted of carcinoma. The tumor was exceptionally well differentiated. It lay fairly well out in the lung parenchyma, without demonstrable invasion of the hilar nodes, and this looks like one of the most favorable cases in the series for cure.

ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION

THE annual meeting of the American Medical Association was held at Atlantic City from Monday, June 8, through Friday, June 12. The gasoline and rubber shortage or fear of the dimout or that Hitler might take the opportunity to get rid of a few thousand physicians did not lessen the attendance or enthusiasm at the meeting. To be sure the boardwalk was not its gay and dazzling self at night, but it was colorful enough in the daytime.

Mr. Paul V. McNutt, administrator of the Federal Security Agency, was the principal speaker at the dinner given in honor of the officers and delegates on Monday evening. His remarks, some-

what misquoted in the daily papers, were forceful and pointed. He said that the Procurement and Assignment Service had been set up largely at the suggestion of members of the medical, dental and veterinarian professions and that these doctors constitute the only group that has been allowed to manage its own affairs in the emergency. He added that he hoped the Procurement and Assignment Service would succeed and that he and his associates would do all they could to keep it working. He admitted, nevertheless, that, up to the moment, not enough physicians had been obtained for the armed services and that if they were not forthcoming in the near future, some means other than the Procurement and Assignment Service must be utilized. His emphasis left no doubt as to his meaning. He addressed the House of Delegates in similar vein at its business meeting the next morning.

The meetings of the House of Delegates were, as usual, well attended and businesslike. There was some agitation to increase the size of the Board of Trustees from five to nine, on the theory that a considerable portion of the country was not represented. It was pointed out, however, that the Board of Trustees was not intended to be a representative body but was designed to conduct the business of the association and that small business boards are usually more efficient than large ones. The House of Delegates declined to authorize the change.

The resolution of the Massachusetts Medical Society regarding prepayment sickness insurance was presented, and the delegates voted to approve the provision of prepayment medical insurance on a medical-service as well as a cash-indemnity basis. The House of Delegates also authorized the Council on Medical Education and Hospitals to set up a program for refresher courses for physicians returning to private practice after the war, to bring them up to date in medical progress. This was accompanied by instructions to the Board of Trustees to urge military authorities to continue to pay full allowance to physicians who desired to take these courses.

The huge auditorium provided adequate space, not only for the scientific and commercial exhibits but also for the section meetings, the former continuing to grow in size and interest each year. All in all, the meeting was well up to its usual standards.

DEATH RATE IN INFANCY AND CHILDHOOD

DURING the past two decades, according to Dublin and Spiegelman,* child mortality in the United States has maintained not only a consistent but a spectacular fall. In 1920, for example, an infant mortality rate of 86 per 1000 live births obtained in the birth registration states of 1917; in 1929, this had declined to 66, and in 1939, to 44. That even greater improvement under continuing conditions of peace and relative freedom from epidemic disease might be expected is shown by the inequality of the general rate, ranging from a recent high of 109 deaths per 1000 births in New Mexico to a low of 37 in Connecticut, New Jersey, Oregon and Washington.

Although, on the whole, infant mortality is lowest in the north central and northwestern states, and highest in the South, it is interesting that Maine, of the New England states, stands alone in its membership among the states with the highest rates—over 50. New Hampshire and Vermont rank in the next group, with a 45 to 49 rate range, and Massachusetts and Rhode Island in the group with rates from 40 to 44. Connecticut is the only state in the most favorable group, with a rate below 40.

It is eloquent of the effects of civilization and economic advance, however, that during this period, for the first time in the history of the United States, an actual decrease in the child population has occurred. Such has been the decline in the birth rate that the number of children under fifteen years of age, which had risen from 33,600,000

in 1920 to 36,100,000 in 1930, diminished to 33,100,000 in 1940, or from 32 per cent of the total population in 1920 to 25 per cent in 1940. At the same rate, the number will have decreased to about 32,000,000 in 1960, or 22 per cent of the total population.

The improvement in child mortality, if not in total child population, is no doubt an index of the general rise in the standards of living, including improved benefits from medical science and public-health administration. It may be that the flood tide in the benefits that science can give to mankind has been reached: standards of living are going to be lowered; materials will be directed into other channels of production; scientific effort will be directed away from the paths of peaceful advance; personnel will be engaged elsewhere.

Greater effort than ever before will be required of those who can still participate in peaceful projects to hold fast to the ground that has already been gained.

MEDICAL EPONYM

POLITZER BAG

Dr. Adam Politzer (1835-1920), while *Docent* in otology at the University of Vienna, presented a discussion, "Über ein neues Heilverfahren gegen Schwerhörigkeit in Folge von Unwegsamkeit der Eustachischen Ohrtrumpete [On a New Therapeutic Procedure in Deafness due to Blocking of the Eustachian Tube]," in the *Wiener medizinische Wochenschrift* (13:84-87, 102-104, 117-119 and 148-152, 1863). A portion of the translation follows:

The seated patient holds a little water in his mouth . . . and is told beforehand to swallow it at a given signal. The instrument used consists of a straight or slightly curved metal tube shaped like a catheter; or better, a rubber tube of rather large caliber, connected with a pear-shaped rubber bag about twice as big as a man's fist. The physician, standing preferably at the patient's right side, inserts the anterior end of the tube 1.0 cm. into the proper nostril, compresses the ala nasi (so that no air can pass over the instrument) with his left thumb and index finger, and with his right hand vigorously expresses air from the bag into the nose while the patient swallows.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

CASE HISTORY: PREMATURE SEPARATION
OF THE PLACENTA, FOLLOWED BY DEATH

A multipara was not seen until she arrived in the hospital when about six months pregnant. Her past history was essentially negative, and she had had no prenatal care. Her first four pregnancies had been normal, and all the children were living. She entered the hospital because of bleeding, which had started as a stain when in the tenth week of pregnancy and had continued off and on as a stain until shortly before hospital entry. Three weeks before admission, she had had a sudden profuse flow with clots, and had stayed in bed at home until she went into the hospital. On entry, she was flowing moderately and continued to flow sufficiently to require six or eight pads a day for the next two weeks and a half. No examination was made during this time, presumably because the pregnancy had not advanced to a point where a viable child was likely to be obtained and for fear of increasing the bleeding by examination. At the end of this time, the bleeding increased, and vaginal examination was done. This revealed no placenta previa, and by the process of elimination, a diagnosis of separated placenta was made. The following day, the membranes were artificially ruptured, the cervix and vagina were packed with gauze, and a Spanish windlass was applied. The next day, the baby and placenta were delivered. Since the placenta did not come away spontaneously, manual extraction was performed and was followed by very free bleeding. An hour and a half after the placenta had been extracted, 500 cc. of blood was administered. Since the bleeding increased, the vagina and uterus were packed with gauze, and a second transfusion was given. Finally, because of continued bleeding, an abdominal hysterectomy was performed, but the patient did not survive the operation. Autopsy showed a postpartum uterus with portions of adherent placenta.

Comment. The history of this case is rather unusual. Throughout the period of irregular flowing, medical advice was not sought until a frank hemorrhage had occurred. Delayed treatment in the hospital for the presumable purpose of securing a viable child was warranted. Furthermore, rupture of the membranes and packing of the cervix and vagina were undoubtedly the method of choice in a multipara at this stage of pregnancy when another hemorrhage demanded surgical intervention. Had the placenta been examined very carefully, it might have been inferred

that the hemorrhage following delivery was due to pieces of placenta that remained after manual extraction. Although the record makes no mention of it, it is also possible that this adherent placenta was a true accreta, and had this been recognized, if such existed, at the time of manual removal, an immediate hysterectomy following the first transfusion might have prevented the fatality.

If this patient had been seen earlier in her pregnancy at the onset of bleeding, it might have been deemed wise to curette the uterus then. If this had been done, the fatality would never have occurred.

DEATHS

METIVIER — **ARMAND O. METIVIER, M.D.**, of Chicopee Falls, died July 2. He was in his fifty-third year.

Born in Canada, he later went to Keene, New Hampshire. He graduated from St. Anselm's College and received his degree from the College of Physicians and Surgeons, Boston, in 1915.

Dr. Metivier was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son, two daughters and four brothers survive him.

WILLOUGHBY — **EARLE C. WILLOUGHBY, M.D.**, of North Reading, died June 23. He was in his sixty-first year.

Born in North Haverhill, New Hampshire, he received his degree from Tufts College Medical School in 1911. He served on the staff of the State Infirmary at Tewksbury until 1917, when he was transferred to the North Reading State Sanatorium. Soon after that, he was made assistant superintendent.

Dr. Willoughby was a fellow of the Massachusetts Medical Society and the American Medical Association. He was also a member of the Southern Middlesex Health Association, the Trudeau Society of America and the National Tuberculosis Association.

His widow and two brothers survive him.

MASSACHUSETTS MEDICAL SERVICE

WIDE INTEREST IN PLAN

All licensed physicians in Massachusetts may participate in the Massachusetts Medical Service, according to Dr. James C. McCann, the newly elected president. Since the public announcement of the launching of the new nonprofit system for the prepaid budgeting of medical care, the headquarters at 230 Congress Street, Boston, have been flooded with inquiries from physicians and laymen throughout the state.

"The chief query from the public," McCann states, "is, When will the service be available? The speed with which doctors participate is the only answer, although early September is our goal. While the first contract is limited to surgery, obstetrics and diagnostic x-ray service, all physicians are urged to pledge their support, even

if they are not involved in the first contract."

Because physicians are asking for more detailed information about the new nonprofit corporation, a series of articles has been prepared by the members of the Central Professional Committee. The first of these, dealing with the corporate structure of the organization, appears below. In the following weeks, the *Journal* will publish articles dealing with service contracts, compensation for professional service, the physician's relation to the corporation, the relation of the Massachusetts Medical Service to hospitals and the enrollment regulations of the plan.

* * *

THE CORPORATE STRUCTURE

JAMES C. MCCANN, M.D.

Voluntarily, the medical profession is altering its economic relations with the public through the establishment of the Massachusetts Medical Service, which is set up as a nonprofit corporation. Complete legal protection for the new endeavor is provided by the corporate structure.

Since physicians are placing control of many aspects of medical practice in the hands of a corporation, they may rightfully ask, How does the corporation function? It will function as does any business corporation. Members of the Executive Committee of the Massachusetts Medical Society constitute the voting members of the corporation and take the place of stockholders. The voting members elect the directors, who, in turn, are the corporation's managers. The voting members can remove the directors from office if there is due cause. The only other restrictions on the directors' powers are those specified in the by-laws, those arising from the state insurance commissioner's interpretation of the enabling act and the by-laws and those arising out of recourse by any party to the courts.

Security of Physicians

It is vital that medical standards relating to the welfare and the rights of physicians be protected when they become involved with the legal complexities of a corporation, and that there be professional supervision of the purely medical aspects of any such plan. This supervision is guaranteed by the fact that the voting members are, themselves, physicians representing the profession of the entire state.

As described in the June 18 and July 2 issues of the *Journal*, the directorate of the Massachusetts Medical Service numbers fifteen members, representing equally physicians who have direct contact with the medical profession through the local professional service committees in the districts, eminent laymen whose practical experience is of great value and outstanding representatives of the subscriber groups.

Vital medical matters might be mishandled by such a composite corporation were it not for the organization and the functioning of the Board of Directors, which is broken into committees assigned to specific tasks. The Executive Committee takes responsibility between the meetings of the entire directorate. The Financial Committee guards the funds and investments. The Actuarial Research Committee compiles data that protect physicians through a sound actuarial procedure. The Interlocking Services

Committee supervises the relation of the two independent but jointly functioning corporations — Massachusetts Medical Service and the Blue Cross. The Central Professional Committee has power to initiate action for the Board of Directors on all vital medical matters, submitting complete medical data as a basis for any action by the board. In effect, the last committee serves as a medical advisory committee to the directorate. Furthermore, any anticipated action by the Central Professional Committee must be reported to the voting members, thirty days before action is taken, and the latter can send resolutions and recommendations to the directors. This assures to the representatives of the profession full knowledge of anticipated action by the directors on medical matters. Such facts will also be available to the Council of the Massachusetts Medical Society, whose resolutions or recommendations to the voting members would carry impressive weight.

The medical profession of Massachusetts is privileged to have serving on the directorate some of the most eminent nonmedical leaders of the state. These men are serving without compensation, because of a sense of responsibility to the public, and have accepted a trusteeship that will require much of their time and expert judgment. Remembering that the corporation is not an insurance company but strictly a corporation formed by them to solve current problems in medical care, physicians are greatly indebted to these civic-minded lay directors.

Opportunity for Plan

Massachusetts Medical Service, established after long years of study and based on the experience of other medical-care plans throughout the country, has the opportunity of meeting changing conditions and, at the same time, of preserving basic freedoms. Patients retain the freedom of choice, and physicians retain the freedom to serve. Through this new corporation, the medical profession of Massachusetts can satisfactorily meet the challenge of the times.

WAR ACTIVITIES

CIVILIAN DEFENSE

AIDS TO DECONTAMINATION

The following letter has recently been released by the Office of Civilian Defense, Washington, D. C.:

Decontamination stations should be of simple construction with ample facilities for disrobing, bathing and chemical neutralization. Persons contaminated with liquid vesicants must be treated within five minutes to avoid severe burns. Complete preparations therefore require that facilities are sufficiently numerous so that every individual is within five-minutes walk of a decontamination station. Gasoline filling stations are widely distributed and may be adapted for this purpose.

Suggestions for adapting gasoline filling stations for decontamination are as follows:

1. Use stations with washing and greasing facilities under cover.
2. Establish a temporary disrobing area outside and adjoining the washroom, shielded by canvas, parked automobiles or some other device providing privacy. Allow abundant natural ventilation. Everyone entering the disrobing area must walk through a box of sand and bleaching powder to decontaminate his shoes (three parts of sand to one part of bleach containing 30 per cent hypochlorite).

- 3 Provide a gas lock to the washroom, with a foot bath of bleach slurry of sodium hypochlorite solution
- 4 Install temporary showers or improvise a pipe with several outlets for multiple bathing. Use hoses operated by attendants for washing large numbers of people. Supply soap
- 5 Eyes should be irrigated with soda near the entrance of the washroom or hosed gently with plain water in the event of large numbers
- 6 Use grease room for dressing
- 7 Partition off the grease room from the wash room with wall board or other temporary material if the rooms are not already separated
- 8 Provide a gas lock between the washroom and the dressing room
- 9 Use the station office or the ladies rest room for first aid, if necessary
- 10 It is advisable to ventilate the wash and dressing rooms by means of ordinary cooling fans blowing out of the windows
- 11 Supply numbered paper, burlap or cloth bags for each person's clothing, and record name and address opposite the number
- 12 Keep contaminated clothing outside the station, and place bags of clothing in covered metal containers until decontaminated
- 13 Provide a supply of clean clothing of assorted sizes in the dressing room
- 14 Apply bleach or sodium hypochlorite solution such as Chlorox, Zonite and so forth as indicated for liquid contamination either in the disrobing room or washroom.
- 15 It is advisable to paint wall board, wood, concrete or brick with sodium silicate paint to prevent persistent contamination
- 16 Consult the Office of Civilian Defense publications *Protection Against Gas*, and *First Aid in the Prevention and Treatment of Chemical Casualties* for detailed instructions

The organization and direction of decontamination services for persons is under the Emergency Medical Service. Decontamination of uninjured persons may be assigned by the chief of Emergency Medical Service to the local health department. Stations for decontamination of persons may be operated under the supervision of public health nurses where physicians are not available. Decontamination of food and water supplies should be assigned to the local health department.

CORRESPONDENCE

TREATMENT OF PATIENTS SUFFERING FROM DIETARY DEFICIENCIES AND PROLONGED EXPOSURE

To the Editor I have just seen a perfectly extraordinary situation about which I think something should be done although I am completely at a loss how to proceed

A thirty-two-year-old sailor just came to my office because of excruciating pain in his legs, for which he wished some morphine. One month ago he was on a boat torpedoed off Cape Hatteras. For thirteen days he was in an open boat, with nothing to eat except hardtack and water. Nine of his companions died before the others were picked up a hundred miles offshore by a coastguard boat. All the ten who were saved had enormously swollen feet and legs, and most of them said they felt dead below the knees. Their bodies were covered with salt water boils, and the skin of their hands and feet was soft and white from constantly being soaked in salt water.

The rescued men were taken to a hospital in Delaware. They were put on a light diet, consisting of milk, as often as they wished one egg a day and one small portion of meat a day, they had all the fruit they wished. The first two or three days they had contrast baths, and then they were started on suction treatment with a glass boot, forty minutes a day, for their swollen feet. They received no liver's yeast, liver extract or other vitamin preparations either parenterally or by mouth. Some including my patient, received sulfanilamide because of furunculosis.

After two weeks of this treatment, my patient decided to leave the hospital as he was not getting any better. The physicians there told him there was nothing that could be done for his painful legs except the boot treatment and eating a lot. They also said that no other treatment was being used anywhere along the Atlantic seaboard, where so many similar cases are being treated in the hospitals along the shore.

My patient is still some 18 to 20 pounds below his weight of a month ago and has absent vibration sense below his ankles that is, over both feet. He has no paresthesia above the ankles but complains bitterly of a dull aching pain in the bones of his feet.

I do not believe there is the slightest doubt that he will eventually have practically complete clearing of all his paresthesia on nothing but an average diet. It seems pretty inexcusable to me, however, to treat men suffering from acute vitamin deficiency with contrast baths and a suction boot without any vitamin supplement orally or parenterally.

My particular patient being relatively young is probably going to get by without any permanent damage from the treatment he received, but I wonder if something should not be done to wake up the medical men responsible for the care given in these hospitals.

DUDLEY MERRILL, M.D.

REPORT OF MEETING

HARVARD MEDICAL SOCIETY

A regular meeting of the Harvard Medical Society was held at the Peter Bent Brigham Hospital on March 10 with Dr. James P. O'Hare presiding.

In a case presented by the Surgical Service, a seventeen-year-old boy entered the hospital half an hour after receiving second-degree and third-degree burns of more than half the body surface in a gasoline explosion. The area was immediately cleaned and debrided in the operating room under Penitrothal anesthesia. An eschar of trinitro acid and silver nitrate was applied to the flat surfaces and tulle gras to the areas where motion was advisable. During the first ten hours the patient was given enough fluid

min and plasma in 12,000 cc. of fluid to equal 8000 cc. of plasma, yet the hemoglobin concentration remained at double its usual value. After twenty-four hours, the face, neck and tongue began to swell dangerously, and multiple Z incisions were made in the neck to relieve the severe constriction. The patient gradually improved and received decreasing amounts of parenteral fluids until the sixth day, when he was able to maintain himself by oral feedings. The burns remained nonseptic, and after several weeks, epithelialization began in several areas.

In discussing the case, Dr. Charles A. Janeway stated that the 100 gm. of albumin, which equals 2000 cc. of plasma, was just sufficient to maintain daily equilibrium at first. The parenteral use of crystalloids not only is disadvantageous but may actually be harmful in that it may increase hemoconcentration and further deplete the plasma protein. This patient, as a result of the albumin therapy, finally reached a state where the total protein value, although normal, consisted of practically all albumin and no globulin. The value of the latter component for many vital substances, notably vitamin K, makes it advisable to change to plasma therapy at an early stage in the treatment of prolonged protein loss. The elevated nonprotein-nitrogen level encountered in this case and other cases of severe burns may be attributable to increased tissue destruction or the hypothetical toxins elaborated in the burned areas. It should be noted, however, that plasma, especially the commercial product, contains appreciable amounts of Merthiolate, which is toxic because of its mercury content. The cost of such therapy is about \$35.00 for 1000 cc. of plasma.

Dr. Elliott C. Cutler, the speaker of the evening, reminded the group that it would require 16,000 cc. of blood merely for the first few days' treatment of this single patient, and therefore questioned the practicability of blood banks as a means of combating mass shock, unless such banks can be conducted on a grand scale. Tanning of burned areas is acceptable and probably preferable on flat surfaces, but is definitely contraindicated where there are creases, where the part is mobile or where an entire circumference is involved, when an eschar may cause interference with circulation or choking, as in the case presented.

Dr. Cutler discussed "The Medical Aspects of Civilian Defense." In emphasizing the need for immediate perfection of home defense, it was pointed out that the United Nations have so far guessed wrong on practically every major move on the part of the enemy, and that our only protection is an all-out preparation. We may even sustain gas attacks, which were abandoned in the assault on England only because of the fear of retaliation. Scrutiny of the trained personnel on hand and the estimated number needed makes it apparent that there is no inadequacy in this respect.

Dr. Cutler reviewed the map of Massachusetts, with its defense regions. Region 5, including Greater Boston with its two million inhabitants and the majority of defense plants, has about 50 per cent of the entire population. The regional organizations are capable of working independently of the central committee. The deputy regional medical officers represent the various medical societies, and these men must therefore be free to work at any time. Dentists are also needed for this purpose, for exact information may often be essential in either medicine or dentistry at the report centers. Hospital superintendents are also being placed in a similar role for organization of institutions.

Cities and towns have their own medical committees, which follow a general plan of organization and action so that the entire group may be integrated in the event of a widespread incident. There are first-aid posts, ideally composed of duplicate units, each with two physicians, two nurses, four nurses' aides and four men trained in first aid. Secondly, there are the first-aid parties comprising lay people, preferably trained in ARP schools and Red Cross courses. In general, it is strongly urged that all the members of all special groups, such as first-aid, wrecking and public-utilities parties, attend an ARP school before taking their postgraduate training in their specialty. Although transportation worries the general population, it is in reality relatively simple. Hospital administration, however, entails a problem. It is necessary to fulfill the requirements of the Governor's proclamation regarding blackouts while attempting to adhere to a strict budget. It is suggested that money not be wasted on unessential embellishments. Plans have been made for the use of certain institutions as base hospitals in the event of bombings in metropolitan areas, but no promise can be given that evacuation from a given place will be to a certain base hospital.

In addition to the central executive committee, there are subcommittees on base hospitals, on the medical aspects of evacuation, of medical examiners, of dentistry, of public health, of liaison with the Red Cross and with the Protection Division, and on pharmacy. The last group has donated all the necessary pharmaceuticals. Certain drug-stores have been designated as auxiliary first-aid supply depots, but they must pass certain requirements.

A brief sketch was given of the course of events if an incident occurs: the role of the interceptor command, which ranges three hundred miles to sea; the meaning and scope of the blue, yellow and red signals; and some of the intricacies and major duties of the many report centers scattered throughout each section. In many of the smaller towns, the medical supply depot, Red Cross depot and casualty station are located together in some central public building, which may also be the report center. The casualty station serves to relieve congestion in necessary hospitals by caring for minor wounded and ambulatory patients. When an incident occurs, mobile medical units (medical first-aid posts and lay first-aid parties) are dispatched to the site by ambulance. The former group sets up the post in some appropriate house or building nearby and determines, according to the extent of the incident, what cases may be treated there and what cases should be transferred to hospitals. These are first sent to emergency hospitals and are then transferred to base hospitals if evacuation of the former becomes necessary.

During the discussion it was emphasized that sulfanilamide powder may be full of spores and is not self-sterilizing. This fact also makes its sterilization in containers difficult, but this has finally been overcome, and the drug is now dispensed in individual sterile containers.

BOOK REVIEW

Roentgen Technique. By Clyde McNeill, M.D. Second edition. 8°, cloth, 329 pp., with 276 illustrations. Springfield, Illinois: Charles C Thomas, 1941. \$5.00.

This book is clear, concise, well diagramed and thorough, especially in its discussion of x-ray technic of the skull. It is a good handbook for roentgenologists and technicians.

CEREBRAL SUBDURAL HEMATOMAS*

A Study of Three Hundred and Ten Verified Cases

DONALD MUNRO, MD†

BOSTON

IN 1933, I¹ read a paper before this society on the diagnosis and treatment of subdural hematomas. This was based on my experience with 62 cases. By 1938, the number of cases that I had studied had increased to 215.² By January, 1941, 95 more cases had brought the total to 310. It is this group that forms the subject of this paper. As my experience has increased, it has become more and more apparent that the accuracy of one's conclusions varies directly with the number of cases from which the conclusions have been drawn. This trite remark is justified by the persistence with which small numbers of cases are published and made to serve as bases for conclusions that are in disagreement with or ignore those drawn from larger and more adequate series.²⁻⁴ Notable among the exceptions to this statement are papers by Browder and his co-workers,⁵ Davidoff and Dyke,⁶ and Ingraham and Heyl.⁷ Examples of its truth are a recent editorial⁸ based on two articles in one of which the author's experience was limited to 48 patients, the other being a synthetic report of 42 cases of which the author himself had seen 2, and a case report⁹ presumably published to help care for injured naval personnel. The last is said to describe a case of "pachymeningitis hemorrhagica," but it presents all the autopsy findings of an intracortical clot. There is no doubt in my mind that personal experience with no less than 100 cases of significant subdural hematomas is indispensable to a competent opinion about the incidence, classification, pathology, diagnosis, treatment and prognosis of this very common condition.

In all the 310 cases reported herewith, the presence of the clot was verified either at operation or at autopsy, and was the only significant, or in mul-

tiples lesions, the most significant, intracranial lesion present. Although the clots were not weighed and the amount of subdural fluid was only roughly estimated, the size of the former and the amount of the latter were always pathologically significant. No case has been included in which the clot or the fluid could, by any stretch of the imagination, be considered incidental either to other findings or in their own right.

The gross pathology of subdural hematomas has been described by Leary and Edwards,¹⁰ Leary¹¹ and Peet and Kahn.¹² Their work, especially that done by Leary, supersedes, amplifies and corrects the findings published by Putnam and Cushing.¹³ Gardner¹⁴ has covered the experimental field, those unfamiliar with his work should consult the original article. It is fundamental and unquestionably accurate. The surgical pathology has been covered by Munro and Merritt¹⁵, increasing experience has confirmed these earlier findings. So far as I know, no comparable studies have been published since then. I have no doubt, therefore, from these data and other evidence, as well as from my own increasing experience, that cerebral and cerebellar subdural hematomas originate as blood and cerebrospinal fluid mixed in varying amounts and incarcerated within the intracranial subdural space.

In conformity with what appears to be a fixed determination on the part of the medical profession to divide subdural hematomas into acute and chronic groups, the cases in this series have been grouped accordingly. However, since attempts to measure the acuteness by elapsed time are as unsatisfactory as they are inaccurate, in both the acute and chronic cases, I have classed those cases as "chronic" in which there was no evidence of fresh or unhealed associated brain injury. Cases that still showed evidence of unhealed or acute brain injury have been classed as "acute subdural hematomas."

*Read by title at the annual meeting of the New England Surgical Society, Hanover, New Hampshire, September 5, 1941.
From the Department of Neurosurgery, Boston City Hospital.

†Assistant professor of neurosurgery, Harvard Medical School; associate professor of neurosurgery, Boston University School of Medicine; surgeon-in-chief for neurosurgery, Boston City Hospital.

Since all hematomas are acute at the start and since they become chronic only because their presence has been unrecognized earlier by the attending surgeon, this distinction, although perhaps valid, seems to me to be unnecessary and artificial.

CHRONIC SOLID SUBDURAL HEMATOMAS

If the hematoma is formed of pure blood, such as that resulting from the rupture of a bridging vein, and if there is no tear in the arachnoid, the hematoma will be expansile only while the bleeding is unchecked. After the bleeding has stopped, the hematoma will clot, and the clot will be encapsulated between two membranes by the growth of fibro-

cause the other contents of the skull have been unable to accommodate themselves to this extra space-occupying lesion. This is the typical subdural hematoma associated with intracranial injury of the newborn² and is the type that develops from nontraumatic cases,—for example, in scurvy and blood dyscrasias,—as well as after craniocerebral injury. It is not necessarily an immediately fatal lesion even when associated with trauma. The patient is apt to have no significant symptoms at the time it is first formed, the injury is liable to be trivial, and the symptoms, when they do develop, are prone to be remissive. Until recently, clots that originated in trauma have usually been over-

blasts on both the dural and arachnoidal surfaces, after which organization of the clot itself takes place from the two membranes. Depending on the relative speeds of organization of the surface and liquefaction of the center of the clot, the latter will be replaced by, at one extreme, a single fibrous sheet representing the fused membranes and organized intervening clot and, at the other, by a collection of fluid with a very high protein content contained entirely within membranous walls that are fibrous and may include calcium. The former is adherent to the dura, and even on microscopic examination may be indistinguishable from it except as a local thickening. The latter appears as a cyst with numerous vascular and fibrous adhesions between its wall and the dura, arachnoid and pia.^{10,11,15} It lies completely within the subdural space. Neither of these lesions is expanding. When they cause symptoms of increased intracranial pressure, they do so only be-

looked at the start and then recognized later only in the course of an investigation of the patient as a "brain-tumor suspect." This has been well emphasized by Horrax and Poppen.¹⁶ It is this group of subdural hematomas that, after having been overlooked and undiagnosed at their formation, have been discovered later and described as "chronic subdural hematomas." If the diagnosis has been even more inaccurate, the patients have been committed to insane hospitals as psychotic, only to have the true cause of their mental abnormalities first recognized at autopsy.¹⁷ This kind of clot was the subject of Putnam and Cushing's¹³ paper, and is the least common of all intracranial subdural hematomas.

Chronic solid subdural hematomas occurred forty-five times in this group of 310 verified cases (Table 1). In 3 cases, an associated diagnosis of "old contusion of the brain" could be made. However, in these, as well as in the other 42 cases, any associated

brain injury that had been present when the clot formed had long since healed by the time the hematoma had been diagnosed. Three cases had demonstrable fractures of the skull. Thirty-eight clots were solid and encapsulated, and seven were

only a trivial craniocerebral injury—many being unaccompanied by unconsciousness even—and the subsequent persistent but often intermittent headaches. Objective symptoms are minimal and, if present, are usually caused by the associated brain

cystic and encapsulated, as described above. In 1 case, two solid clots were present. They were discrete, superimposed one on the other and both in the right parietal region. A fresh hematoma was present in addition to a chronic one—both being solid clots—in 1 case. In 1 case, the clot was calcified, and there was 1 in which simultaneous

damage and toxic dehydration. Later on, the subjective symptoms and signs are those of a brain tumor suspect. There is not necessarily any evidence of increased intracranial pressure. The diagnostic use of air in these so-called "chronic" cases by both the ventricular and lumbar subarachnoid routes has been recommended by Kun-

right parietal, right occipital and right frontal clots were present, the parietal clot recurring after removal. A ruptured bridging vein was identified as the certain source of the clot in 2 cases. Both these patients died of circulatory failure and were autopsied, one having been operated on previously

and Dandy,¹⁸ Browder et al,⁵ Horrax and Poppen¹⁰ and, doubtless, many others. It is unquestionably of great and often indispensable aid. I have never approved either the need or the safety of its use in the acute phase, however, preferring bilateral transtemporal exploration.

Diagnosis

Early diagnosis of this type of hematoma depends on the recognition of a significant cause-and-effect relation between what may be considered

Treatment

Treatment is surgical, with removal of the solid, partially organized clot, and as much as is safe of the fused membrane that is the end result of com-

plete organization. Cysts should be emptied, and as much of the walls removed as is compatible with safety. In children, it is essential, as Ingraham and Heyl⁷ have shown, that the membrane, and especially the one that lies on the arachnoidal side of the clot, be fully removed if later stunting of the growth of the hemispheres is to be prevented. The operation, which should be done by way of a flap craniotomy, is apt to be bloody, and post-operative clots and severe cerebral edema are frequent complications.

Immediate Results

There were 15 deaths in this group of 45 cases — a mortality of 33 per cent. All except 1 patient were operated on. The causes of death are interesting (Table 2). Circulatory failure was the commonest. This was present nine times. Medullary edema was considered to be the cause of death in 3 cases, hydrocephalus in 1, a recurrent clot in 1, and lobar pneumonia in 1. The clots were present on the left, the right and bilaterally each five times. Two of the hematomas recurred after operation, and another was calcified. Twelve deaths occurred in the group of solid clots, and 3 in the cystic-clot group (Table 3). Two of the latter were the result of birth injuries, in one of which, no operation was performed, and the other was present in a man of sixty-seven. In this connection, it may be

group was twelve years less than that of the fatal cases — thirty-eight as compared with fifty years. It seems fair to conclude that the prognosis in the group of chronic solid cerebral subdural hematomas is altered to some extent by the age of the patient but not by any other specific factor. It is impossible to determine the rate of incidence of this class of cerebral subdural hematomas among craniocerebral injuries in general.

ACUTE MIXED SUBDURAL HEMATOMAS

When both blood and cerebrospinal fluid collect and mix in the intracranial subdural space, the appearance of the resulting clot varies within wide limits. Macerated cortical tissue may also be added to the mixture. If the blood is at a maximum and the cerebrospinal fluid at a minimum, the clot closely resembles that described above as an "acute solid hematoma" — the variation being chiefly in the length of time that elapses before the blood solidifies. If, on the other hand, there is a maximum of cerebrospinal fluid, and a minimum of blood, the mixture and subsequent solution of the latter in the former preclude all attempts on the part of the dura to organize the hematoma. The hematoma is represented, therefore, by a collection of pigmented fluid with a high protein content. It is incarcerated in the subdural space but is, nevertheless, free to move anywhere within that space. It requires no great stretch of the imagination to visualize the change that variations in the relative concentration of blood and cerebrospinal fluid might make in color, consistence, and rate and completeness of coagulation in this type of hematoma. So long as coagulation and, therefore, organization by encapsulation do not take place, this blood dissolves in the cerebrospinal fluid that has escaped into the subdural space. This solution is separated by a dialyzing membrane — the arachnoid — from another solution (the cerebrospinal fluid) that has a relatively low protein content and a low osmotic pressure in relation to the hematoma. Under such circumstances, osmosis, with migration of the fluid of low protein content across the membrane to, and consequent dilution of, the solution of high protein content, is inevitable. With this movement and as the direct result of it, there is of necessity an increase in the amount of the high protein solution. This type of subdural hematoma is therefore an expanding lesion during the periods of solution and osmosis. The rate of expansion, which is rapid for the first five weeks, gradually decreases over the next two months as the concentration of protein in the two solutions approaches equality. This sequence of events has been demonstrated experimentally by Gardner¹⁴ and by a graphic study of eighty-nine such fluids by Munro.² Browder et al.⁵ consider my "theoretic explanation

TABLE 4. *Age Groups.*

Dead patients	10 months	67 years	40.5 years	19
All patients			40.5 years	116

noted that the average age of this group of fatal cases was fifty years, the youngest being ten months and the oldest sixty-seven years (Table 4).

All the 30 living patients had been operated on. Ten clots were on the left side, thirteen on the right, and seven bilateral. One recurred and was removed at the second operation (Table 3). Although the youngest patient was nine weeks and the oldest sixty-six years of age, the average age of this

that a subdural hematoma may be augmented by osmosis in a certain number of such lesions" entirely logical. They find it difficult, however, to explain certain variations in the consistence and color of different clots that have been present the same length of time after the injury. This finding has been my experience also, but unlike them I find no difficulty in accepting the explanation that, although the time interval is the same, the relative amounts of blood, cerebrospinal fluid and cortex are highly individual and should therefore produce hematomas no two of which can be alike.

This mixed type of subdural hematoma occurs exclusively as the result of craniocerebral injuries. In addition to damage to blood vessels on the brain surface, there is always a tear in the arachnoid. Thus, as noted above, in addition to blood, cerebrospinal fluid is discharged in varying amounts into the subdural space. The blood is commonly from cortical veins, less often from the large venous sinuses and less often still from cortical arteries. I have never seen the latter, but Browder and his associates⁶ report its occurrence. If the injury has produced a laceration of the pia and the brain, cortical tissue may also be added to the blood and cerebrospinal fluid. Since these patients have, as a rule, severe brain injuries in addition to their hematomas, since many of them are in surgical shock for a varying period after the receipt of the injury and since these hematomas are expanding lesions, there is an associated compression of the brain that is beyond that which may be produced by uncomplicated cerebral injury. This group of patients has the highest fatality rate. In general, they are the ones who are first treated for a lacerated or contused brain but who despite that therapy get worse and often die with the clot unoperated on and undiagnosed. The prognosis is not invariably fatal, however, even in the absence of active therapy. Many patients, especially those whose hematomas contain less rather than more blood in relation to the amount of cerebrospinal fluid, recover from the immediate effects to become chronic invalids until such time as their fluid subdural hematomas or, as many are improperly called, their "hydromas" are removed. Early diagnosis and early treatment of the mixed subdural hematomas obviate this difficulty and save many lives in addition. It is this mixed type of subdural hematoma that is far and away the commonest of the subdural clots. If real progress is to be made in the reduction of the immediate mortality of craniocerebral injuries and the elimination of later disabling post traumatic neuroses and invalidism, the attention of the medical profession must be concentrated on this group of cases to a much greater degree than it has been in the past.

In this group of 310 cases, 194 had acute mixed subdural hematomas. These were complicated by a recognized associated major brain injury in 184 cases. Its presence was verified at operation or autopsy in every case. No note of any brain injury was made in the other 10 cases. A fracture of the skull was demonstrated in 55. Forty five of these were simple, seven were depressed, and three were compound fractures. Nineteen cases had other major complicating hemorrhages. Eleven were extradural, seven subcortical, and one ventricular. Toxic dehydration was present in 6 cases. No clots could be traced to ruptured bridging veins (Table 1). Six patients had infected wounds.

Diagnosis

I am convinced that a certain diagnosis of the presence of a mixed subdural hematoma can be made only by exploratory trephination. The next most accurate method is by either an encephalogram or a ventriculogram. I consider an encephalogram too dangerous a method to be used in these acute cases, and mention it only to condemn it. I see little to choose between the risk of a ventriculogram and an exploratory trephination. Since my experience leads me to believe that explorations made in areas other than the temporal miss a certain percentage of temporal and frontal clots and since exploration together with ventriculography forces the operator to make biparietal or bifrontal trephines, I have never felt justified in using air in this way in these cases. Aside from the operative demonstration of a subdural collection of blood, the most important diagnostic aid is to recognize the presence of a brain injury, treat it adequately, and then be prepared to carry out a transtemporal exploration if the patient fails to improve or gets worse under nonoperative therapy. Of course, before exploration, toxic dehydration must also be eliminated as a cause of the continued symptoms. The subjective and objective symptoms produced by these hematomas cannot be distinguished from those caused by either an uncomplicated brain injury or toxic dehydration. Lateralizing signs are notoriously inaccurate. The cerebrospinal fluid is altered from normal only because of the brain injury, and its pressure may be high, normal or low, even in the presence of a large clot. I have not seen any dependable regularity in the development of coma or a latent interval and do not regard their presence or absence as being of any diagnostic import. I have the impression that lasting mental changes and the development of a contralateral central facial palsy while the patient is under treatment are commoner in the presence of mixed subdural hematomas. Unilateral fixed dilatation of the pupil is a suggestive

diagnostic sign, but it is not reliable.¹ Exploratory trephination, transtemporal by preference and bilateral if necessary, is never contraindicated in a patient who has been knocked unconscious by a blow on the head and who is not getting better or is getting worse under adequate lumbar-puncture and fluid therapy.

Treatment

Just as in the cases of solid hematoma, the treatment of the acute mixed hematoma is exclusively surgical. The operation should not be done while the patient is in shock or toxic from dehydration, but otherwise should be carried out in accordance with the requirements noted above. When a hematoma is found and no matter what its physical consistence may be, it should be removed by suction as completely as possible after the majority of the squama and the adjoining edges of frontal and parietal bones have been removed and the dura opened to the limit of the bony windows. Afterward, the subdural space should be drained with rubber tissue and the dura left open. The rest of the wound should be closed in layers. Irrigation of the damaged cortex should be studiously avoided. The approach should be through a vertical muscle-splitting temporal incision. I consider bone flaps contraindicated and too dangerous. It should be noted, however, that Browder and his associates⁵ advise and use small bone flaps with apparent satisfaction and success in this type of case. The postoperative care of these patients requires as much judgment and skill as the operative procedure—indeed, more in many cases. The brain injury must be treated, and in addition, the need for intelligent general supportive measures is more than ordinary. Finally, malignant postoperative edema is very prone to develop and unless treated with all the means at one's command will bring about a fatal ending to an otherwise successful case.

Immediate Results

Seventy-nine of the 194 patients with acute mixed subdural hematomas died in the hospital. This is a mortality of 41 per cent. Since all patients were operated on, the operative mortality is essentially the same. The causes of death in the fatal cases are interesting and particularly so when compared with the cause of death in the fatal cases of solid hematoma (Table 2). Circulatory failure was again the chief cause, having occurred in 29 cases. Next, came medullary edema, with 27. Pneumonia and meningitis caused 5 and 6 deaths respectively; in 4 of the 6 cases with meningeal infections, the complication occurred postoperatively. Surgical shock caused 4 deaths, recurrent un-

recognized clots, 2, and respiratory obstruction, uremia and empyema thoracis, 1 each. In 1 case, the cause of death was not clear. Eleven patients died without operation. All were autopsied, and the cause of death determined thereby. Fifty-eight clots were unilateral, twenty-eight being on the right and thirty on the left. Fourteen were bilateral, four recurred, and 2 patients had a combination of old and new clots. There were no multiple clots. Four hematomas were fluid as distinct from the liquid and solid clots in that there was no gross solid material present. Seventy-six were cerebral, one was cerebellar, and the location of two was not given (Table 3). The youngest of the patients who died was eleven months, the oldest seventy-seven years, and the average age was fifty years. In 3 cases, the age was not known (Table 4). The immediate effects of the operative procedure, as represented by medullary edema, postoperative infections and circulatory incompetence, were major factors in determining the number of fatalities. Of these, the last is the only one with prognostic significance under the circumstances and, when taken in conjunction with the ten years' difference in the average age of the fatal and nonfatal groups, emphasizes again that the older the patient with a subdural hematoma, the worse the prognosis.

One hundred and fifteen patients with acute mixed subdural hematomas survived and left the hospital relieved of the symptoms that brought them in. In 75, the clot was unilateral, forty-one being on the right and thirty-four on the left. Nineteen were bilateral. In 5 cases, both old and new hematomas were present. In 1, they were bilateral—that is, four clots; in 1, one clot was on the right and the other on the left; in 1, both clots were on the right; in 1, both were on the left; and in 1, a fluid clot was present in association with a solid right-sided hematoma. Four clots recurred after operation—one bilaterally and three on the right side. Twenty-one were fluid in type, being unlimited in their freedom of movement within the cerebral subdural space. The total protein in 14 of these and in 2 of the 4 similar fatal cases ranged from 4020 to 56 mg. per 100 cc., with an average of 396 mg. In 3, the fluid clotted before it could be examined. All one hundred and fifteen hematomas were cerebral (Table 3). As in the group of solid hematomas, the average age—forty years—was ten years less than that of the corresponding patients who died. The youngest patient was four months, and the oldest sixty-eight years (Table 4).

CHRONIC FLUID SUBDURAL HEMATOMAS

When the fluid type of mixed subdural hematoma—that is, the type made up of a maximum

of cerebrospinal fluid and a minimum of blood—is allowed to go untreated until after the acute brain injury is healed, it may be said to have become chronic. This is in accordance with the definition of chronicity as given above. Depending on its size, the amount of dissolved blood, the percentage of protein originally contained within it and the length of time that has elapsed between its formation and its discovery or operative removal, it may still be either an expanding lesion and increasing in amount or fixed in relation to both its protein content and its size. In either event, it will be, as it has been from the beginning, incarcerated within the subdural space but free to move anywhere within those limits. I¹ have described these hematomas in detail elsewhere and need not repeat the description here. Others have also described them, but, in my opinion, incorrectly—as “hydromas.” Hydroma or hygroma is defined as a ‘sac, cyst or bursa distended with a fluid’.¹⁰ This term is therefore only descriptive and carries no pathological significance. The term was first applied to subdural fluid accumulations by Naffziger²¹ before the problem of subdural hematomas was understood. Its continued use, as advocated by da Costa and Adson²² in the mistaken belief that a hydroma is a separate entity and not one form of subdural hematoma, is not justified. Their failure to explain how air put into the subarachnoid space can reach the subdural space and outline fluid therein *after* the tear in the arachnoid has closed and incarcerated the fluid, and particularly when the latter is enclosed within cyst walls as well, is a fatal omission. There seems to me to be a need for a clearer understanding of the entire subdural hematoma problem rather than for the identification of another pathologic entity.

Suffice it to say that, just as with the chronic solid clots, so these chronic fluid clots would not exist had their presence been suspected and verified at the time of the original craniocerebral injury, because they are all the direct result of such injuries. This extremely disabling but nonfatal condition is always caused by an injury to the head. The symptoms are those commonly described as being caused by post-traumatic neurosis or malingering, and are usually associated with a severe and persistent true neurosis. If untreated, the patients become hypochondriacal invalids and permanent charges on the community. They do not go insane, nor do they die as the result of this condition.

This type of hematoma occurred in 71 of the group of 310 patients. None had any associated brain injury at the time of examination, although it was possible to demonstrate a simple fracture of the skull in 2 cases. Complications that were frequent in the other types of subdural hematomas

were conspicuous by their absence. On the other hand, there was an unduly large preponderance of the type of condition that suggests permanent brain damage. For example, 14 cases had convulsive seizures, 10 had intellectual changes classified as “encephalopathy,” 1 had optic neuritis, and 3 had hysteroneuroses (Table 1).

Diagnosis

A correct diagnosis can be made only at operation. Air injection is of no help, as has been shown by von Storch and Munro.²³ The cerebrospinal fluid is normal, as is the intracranial pressure. Objective and subjective signs and symptoms are conspicuous by their absence—their presence being significant from a prognostic rather than a diagnostic point of view, the occurrence of convulsive seizures being especially unfavorable. In general, the statements made in this regard in an earlier paper¹⁰ still hold true.

Treatment

The treatment is surgical. The operation should be done as soon as possible after the receipt of the injury, since the shorter this interval the greater the chance for a permanent cure. The subdural space should be exposed through a transtemporal approach, as described above. The approach need be only on one side, preferably that opposite the speech cortex. As much as possible of the fluid hematoma should be removed, and the subdural space drained with rubber tissue. The wound is closed in layers except for the dura, which should be left open. There are usually no postoperative complications, and the patients have immediate and permanent relief so far as their associated neurosis and permanent cerebral changes allow.

Immediate Results

Four of these 71 patients died—2 of lobar pneumonia, 1 of progressive encephalomalacia and circulatory failure, and 1 of heart failure and chronic alcoholism (Table 2). Their ages were forty three, fifty nine, eight and a half and fifty five years respectively—an average age of thirty-one years (Table 4).

Sixty seven patients survived. Eight were not relieved of the symptoms for which they had been operated on. The youngest was five months, and the oldest sixty two years, the average age being thirty years (Table 4). For what they are worth, the comparative figures demonstrate that in this type of hematoma, age has little effect on prognosis so far as mortality is concerned.

DISCUSSION

This series of 310 major subdural hematomas demonstrates that no less than 62 per cent of intracranial subdural hematomas can be recognized

in their acute stage. If they are so recognized, the mortality can be expected to be in the neighborhood of 40 per cent.^{5, 24} It varies with the patient's age and the efficiency of his circulation. So far as the individual types of hematomas go, the fatalities show a consistently higher age level. It seems reasonable to conclude that increasing age is a detriment to the patient in the acute phase of this disease but has little influence on the mortality when the chronic forms are considered. The

lished.² The incidence in this particular group is 13 per cent, but my series is undoubtedly "loaded" because serious and operable cases gravitate toward and mild and nonoperative cases away from my service. I cannot account for the discrepancy between these figures and the 1 per cent incidence reported by Browder et al.⁵ My mortality, on the other hand, is essentially identical with his—41 per cent. In my series, of course, this refers only to the acute mixed

additional prognostic significance of inefficiency of the circulation is of equal importance. This is only too evident from the figures in Table 2 and particularly so if one adopts the broad point of view, which recognizes that medullary edema and hyperthermia are at least closely linked to changes in the circulation. Miscellaneous complications occurring in this series are listed in Table 5. They are of no great significance except so far as alcoholism and syphilis are concerned. As is well known, both syphilis and alcoholism have been held to be major if not exclusive causes of cerebral subdural hematomas. This series demonstrates conclusively that their presence is merely coincidental. Their single possible etiologic connection has to do with alcoholism, and this is recognizable only because a person who is drunk is likelier to injure his head than a sober one.

Cerebral subdural hematomas may be expected to occur in about 10 per cent of all hospitalized craniocerebral injuries. This incidence is considerably less than the figures I have previously pub-

hematomas and predicates a willingness to do early and frequent diagnostic transtemporal trephinations. No attempt has been made to determine the details of the causative accidents or the sex of the patient. An unrecognized and improperly treated subdural hematoma is as fatal in a woman as it is in a man, and it is of little moment, so far as diagnosis and prognosis are concerned, whether it followed an automobile accident, a kick by a horse or a fall from a window. The important thing is to treat the condition early and adequately, and thereby reduce to a minimum the so-called "chronic" hematomas with their associated disabling symptomatology and at the same time lower the mortality of the acute cases.

CONCLUSIONS

In general, it is undoubtedly true that the commonest intracranial subdural hematoma is the mixed type and that the cause for its formation is trauma to the head. The presence of a cerebral subdural hematoma, regardless of its variety, does

not necessarily lead to a fatality. When the patient survives the immediate effect of the injury, the hematomas inevitably cause later symptoms. These symptoms will be disabling, interfere with the economic efficiency of the patient, and lead to a permanent neurosis, which may be associated with permanent structural changes in the brain. Such tragic late effects are preventable if the physician who sees the patient at the time of the original craniocerebral trauma bears in mind the fact that if patients with only contusion and laceration of the brain are adequately and promptly treated they will get better and be freed of their major symptoms rapidly. If such patients fail to get better, or get worse, however, the responsibility rests with the physician to recognize the possibility that a mistake has been made in the diagnosis and that, as a result, he must investigate and treat the cause of this failure to recover by every means at his command.

INSTRUCTION OF LAYMEN IN THE EMERGENCY
SPLINTING OF FRACTURES

BOARDMAN M. BOSWORTH, MD*

NEW YORK CITY

ACCIDENTS do not happen at carefully chosen sites. They are apt to occur under conditions in which medical aid either cannot be obtained or can be had only after a prohibitive lapse of time. Such accidents take place in the woods or fields incidental to hunting and sports, or on highways in thinly settled districts. There is now the added possibility of large scale public disaster, explosion, bombing or invasion in which medical facilities, although immediately available, are temporarily overwhelmed.

The present state of national emergency has stimulated in the general public an unprecedented interest in the handling of accidental injuries, an interest that is well attested by recent dramatizations of first aid treatment in popular magazines. In the past, lay education along these lines has been neglected by the medical profession, with the exception of certain relatively small select groups, such as the Red Cross and Boy Scouts. Now

comes a sudden demand on instruction of civilian defense groups of emergency injuries must be met and is being met out the country, who are out time and energy, chiefly by the American Red Cross and lay groups in the emergency.

To many a physician seem new and strange enthusiasm and will, with thorough mastery with some knowledge of physics, specialist of learning, trained to positive memory, is presented to them the instructor must avoid other pitfalls, effectiveness the

*Assistant surgeon, New York City Hospital; assistant surgeon, Outpatient Department, St. Luke's Hospital; surgeon, Outpatient Department, New York Hospital.

Use simple language—burden your audience with as few technical terms as possible.

Repeat, and repeat again, a few essentials—do not try to cover a mass of details.

Emphasize basic principles so that the student will understand clearly what it is that he is trying to do.

In choosing among several methods of first-aid treatment, present only the simplest effective one.

Be practical—present actual in preference to hypothetical cases, and confine yourself to the real limitations of the case presented and be sure that the method described can be used in the situation under consideration.

Since fractures make up a great part of all accidental injuries, the problem of giving instruction in emergency splinting naturally assumes considerable importance. At first glance, the subject of splinting seems to be an easy one to teach. But as one examines it more closely, certain difficulties

FIGURE 1. *The Pull of a Rubber Band over the Ends of a Broken Stick Illustrates Muscle Pull on a Broken Bone.*

appear. The rationale of splinting is, of course, simple to explain. The pull of a rubber band over the ends of a broken stick suggests the effect of muscle pull on a broken bone (Fig. 1). The rubber band causes each fragment of the stick to slip past the other; with a broken bone, on the other hand, the proximal end is fixed by the body so that the distal fragment tends to be drawn past the proximal. The potential damage to soft tissues by the knifelike ends of bone fragments that have not been splinted can be readily demonstrated, as can the salutary effect of a properly applied splint (Fig. 2). But, presumably, the layman will have no Thomas, Murray-Jones or Keller-Blake splint

available, nor will he have at hand an adequate supply of flannel, muslin and gauze bandages, basswood splints, tongue blades, safety pins, rope and adhesive tape. What can he do?

It is no answer to urge that first-aid kits and splints be carried in every car and kept in every home. This worth-while objective may some day become a reality, but for the present it will not solve the first-aid worker's problem. Instead, he must be

FIGURE 2. *Soft-Tissue Damage Resulting from Transportation without Splinting Compared with Bone Fragments Controlled by an Adequate Splint.*

shown that these materials, although desirable, are by no means essential and that adequate splinting can be achieved quite simply and effectively by using such things as may be at hand or close by. In short, he must be taught to improvise. This calls for ingenuity and imagination in the instructor quite as much as proficiency in technic and experience in teaching.

During the last six months, under the auspices of the New York and Brooklyn Regional Fracture Committee of the American College of Surgeons, a motion picture in color, demonstrating for the layman the emergency splinting of fractured arms, legs and spines, has been produced.* The film is designed to show how an effective splint can be improvised and applied by anyone in a few moments, under emergency conditions, only materials ordinarily available near the scene of an accident being used. The experience gained during the production of this picture may be helpful to others who have volunteered to teach first aid for fractures.

The methods of splinting described below are not necessarily the best, but they have been tested

*"Splint 'Em Where They Lie!" A 16-mm. Kodachrome motion picture in two parts. Part I: Fractures of the extremities (400 feet). Part II: Fractures of the spine (200 feet). The films may be obtained, through the author of this paper, for exhibition to lay or professional groups.

and found effective. Above all, they have one outstanding virtue: they are extremely simple, easily taught and well remembered. Modifications and improvements will undoubtedly occur to many. Certainly, no claim to originality is made. Rather, the basic idea throughout is to suggest what may be used for splinting and thus to stimulate the imagination and originality of others. The following description of emergency fracture care is an outline of the subject in a form suitable for presentation to lay groups.

DIAGNOSIS

The first task the physician instructor has to face is teaching diagnosis. In most cases, the layman cannot be expected to know whether or not a fracture is present unless he makes some kind of examination. Besides, the victim may be unconscious or drunk, or too badly frightened, be bewildered or hysterical to co-operate intelligently. More significant is the fact that an examination may disclose the presence of other fractures, which might easily be overlooked in the enthusiasm and excitement of getting to work on the victim. It is only natural for the novice to concentrate his attention on an obviously broken arm or leg, unaware that the victim has also sustained the far more serious injury of a fractured spine. The possible dire consequences of such an error can well be imagined. The layman must therefore be taught some simple but thorough method of examination, and the instructor should insist that he apply it before undertaking first aid measures as such. Rarely do conditions justify a reversal of this procedure.

What should the examination include, and how comprehensive should it be? Specifically, just what should the layman be trained to look for? In fractures of the extremities, certain cardinal signs, such as local pain, tenderness, loss of function and gross deformity, are readily determined. Search for them can do the victim no harm, and their presence should at least make the layman suspect a fracture. He should also be taught that the peculiar grating sensation, known as crepitus, produced by broken bone fragments, and abnormal freedom of motion in one extremity compared with the opposite are major signs that are present in many fractures. But, at the same time, he must be strictly cautioned that many fractures exhibit neither the one nor the other and that attempts to elicit them are not only unnecessary but are to be severely condemned as being apt to do much harm.

Fractures of the spine often present special difficulties in diagnosis, even for the trained physician. Any great degree of accuracy in their recognition by laymen, therefore, is not to be ex-

pected. Local pain, tenderness and disability are inconstant and unreliable. Paralysis or anesthesia of the extremities, or both, if present, are significant but must by no means be considered essential for a diagnosis. After these facts have been pointed out to the layman, it is well to stress the value of treating as an actual spine fracture any injury to the neck or back that presents one or more of the signs mentioned above.

The layman must be taught the necessity of recognizing shock early and of becoming thoroughly familiar with its ordinary manifestations: pallor, weakness, faintness, cold clammy extremities, weak pulse and shallow respirations. He should approach the problem of diagnosis calmly and with assurance. He must take what time is necessary for a thorough and systematic, but gentle, examination. This is far more easily said than done at the scene of an actual accident. The volunteer is often subject to interference by anxious relatives and importunate bystanders, who demand action of some kind immediately and deprecate his efforts to ascertain first the nature and extent of the victim's injuries. The first aid worker must not allow himself to become disconcerted by this well meant but unfortunate pressure. He must proceed deliberately in spite of it until he has concluded a satisfactory examination and determined the number, kind and severity of the injuries present.

FIRST AID CARE

Fractures in General

The general condition of the victim of an accident should receive first attention. Following a major fracture, a person may or may not be in great pain; however, he is practically always suffering from some degree of shock, and simple measures to combat this condition should promptly be initiated. Among these may be mentioned covering the victim with coats or blankets to preserve body warmth. The administration of mild stimulants, such as hot coffee and tea, although advantageous, is usually impracticable under the circumstances of the accident. If the victim is kept warm from the outset, however, much will have been accomplished. In addition, splinting and immobilization of the fracture will, of themselves, tend still further to reduce shock. Active bleeding must, of course, be controlled at once, but this is a separate subject and lies outside the scope of the present discussion.

Regarding the emergency handling of compound fractures, physicians themselves are not agreed. My own conviction is that the layman should be taught the difference between a compound and a simple fracture and the reasons, chiefly, potential contam-

ination and infection, for the greater seriousness of the former. He can also be shown the risk of converting a simple into a compound fracture by transporting the victim without proper splinting (Fig. 2). As a matter of practical expediency, I believe he should be taught to apply a traction splint to any fracture of a major extremity, simple or compound, before attempting to move the victim.

Fractures of Extremities

In a fracture of an arm or leg, while one person is concerning himself with the general condition of the victim, another should steady the fractured extremity. He should stay with the victim and continue the support while others seek a suitable splint. Material that will serve as a splint is usually the most difficult part of the required equip-

Application of the splint is a relatively simple matter. In place of bandages, rope and adhesive, various articles of clothing can be used effectively. For example, if an old board is used to splint a fractured thigh, it can be applied as follows (Fig. 3). A coat is slipped between the victim's thighs with the neck of the coat toward the crotch, and a loop is loosely fashioned about the upper portion of the hip by knotting the ends of the sleeves together. A folded hat is placed between coat and crotch to ease pressure against the latter when the splint is tightened. The upper end of the board is then engaged in the loop formed by the coatsleeves. At this point, a smooth, steady pull is exerted on the foot by the assistant, who has been steadying the injured extremity. This pull, once begun, must never be relaxed until the splint has been applied and finally adjusted.

Two neckties, knotted together to form one tie of double length, are looped over the ankle, which has been padded with another folded hat or other thick material. The neckties are then passed along each side of the foot and over the lower end of the splint, where they are tied tightly together. The loop thus formed is tightened by means of a small stick passed through it and twisted over and over. The stick is kept from untwisting by a handkerchief tied around it and the splint. The necktie loop should be tightened in this manner until the broken bone is steadied. Further tightening beyond this point is not only useless but dangerous to the circulation. Thus, traction, or pull, has been provided to overcome muscle spasm, but this is not enough.

The thigh and leg must be wrapped securely to the splint to support the extremity and prevent motion of the broken bone. The rest of the coat, whose sleeves are serving as a traction loop, is wrapped snugly about the thigh and splint. Garters, suspenders or neckties are passed around it and fastened for additional support. In similar fashion, the leg is wrapped to the splint, a vest, shirt or another coat being used. The splinted leg may then be lowered, but one must keep the heel of the foot off the ground by resting the lower end of the splint on a stone or other support. This avoids painful and dangerous motion of the bone fragments. It should be emphasized that only then is the fracture victim ready to be moved from where he has fallen. When the victim is picked up, the foot of the injured extremity should never be lifted; one should always lift the splint by which it is supported. Similarly, when the victim is placed in a car for transportation, a support for the end of the splint is arranged so that the foot hangs free, suspended by the splint. These simple precautions greatly minimize pain and shock.

FIGURE 3. *Emergency Splint for Fractured Thigh or Leg, Improvised with an Old Board and Articles of Clothing.*

ment to improvise under emergency conditions, and yet at times it may be surprisingly easy. A fence rail, signpost, fallen tree, broom, rake, rifle, skipole or ski is adequate, and other materials may suggest themselves. Under certain conditions, such as darkness, storm and freezing cold, more harm than good may result from the delay caused by seeking a splint, and it may be much wiser simply to bind one leg to the other or the arm to the body than to run the risk of increased delay and exposure to a seriously injured and weakened person. Each case must be considered on its merits, and if there is any real question between life and limb, the issue must, of course, be decided in favor of the former.

Ideally, the splint should be light but strong. It must be of sufficient length to reach from above the shoulder to well below the hand in a patient with a broken arm, or from above the hip to considerably below the foot in one with a fractured thigh or leg. It is much better for the splint to be too long than too short.

A broken arm can be provided with an emergency splint in much the same way (Fig. 4). One assistant steadies the arm by taking a firm grasp of the hand. Pull on the arm must not be so strong as pull on the leg, since the muscles are weaker. A coat is slipped between the arm and

FIGURE 4. Broken Arm in Emergency Broom Splint.

Note that a coat is thrown over the body to keep the victim warm.

the body, and its sleeves are looped above the shoulder, as described above. A folded hat or other pad is placed in the armpit to relieve pressure, and the upper end of the improvised splint is engaged in the coatsleeve loop. Neckties, looped over the wrist, which has been padded with another folded hat, are tied over the lower end of the splint and tightened with a small stick just sufficiently to steady the bones.* The stick is again held in place with a handkerchief tie, and another handkerchief, loosely tied about the splint, gives the hand support. The arm and forearm are then

wrapped to the splint exactly as in the treatment of a broken thigh.

Fractures of the Spine

When one presents this part of the subject, it is well to make sure that the layman understands clearly what the spine is, in general how it is constructed, and what purposes it serves. He should be shown, with a rough sketch or two, that it is made up of a number of small blocks of bone, of more or less equal size and shape, placed one on top of another in a tall column (Fig. 5). The instructor should point out that the function of the

FIGURE 5 Anatomy of the Spine and Cord, Simplified to Show the Mechanics of a Fracture of the Spine.

spine is not only to support the body but also to protect a large bundle of vital nerves—the spinal cord—that connect the brain with the rest of the body. This should be sufficient anatomy. Any attempt to give it in more detail will confuse the listener and interfere with a clear grasp of the subject. After all, time, as well as the average mental capacity, is limited.

Having laid this groundwork, one should explain the mechanics of injury. Sudden, violent for-

*It must be emphasized in no uncertain terms to a lay group that major blood vessels and nerves lie close to the surface in the armpit where they are extremely vulnerable to pressure. Not only must the armpit be well protected with padding but also great care must be taken not to apply excessive traction by turning the small stick up too tightly. Paralysis resulting from overpull is a real danger that must not be forgotten. Pull should not exceed 4 or 5 pounds and when there is doubt, it is far better to have the Spanish windlass too loose than too tight.

ward bending of the spine, as in a fall from a height or in an automobile collision, should be stressed as the usual cause of such fractures. The possibility of damage to the cord should be given as sufficient reason for treating any suspected back injury as a fractured spine, and forward bending of the spine, during handling of the victim, should be avoided for the same reason.

Concerning the exact method the layman should be taught in dealing with a suspected spinal

FIGURE 6. *Method of Moving a Victim with a Fracture of the Neck to an Improvised Stretcher.*

injury, there is room for some difference of opinion. Although details may vary, the underlying principles remain the same. Here again, in my opinion, simplicity should govern. After the victim's general condition has received attention, some strong flat support on which to place him must be found. This may be a board, shutter, door or other large flat object. It should be nearly body length or longer. Securing an adequate support of this kind often proves difficult, and it may be necessary to go some distance to find anything that will serve. Weather and the victim's general condition permitting, however, the effort should be made. Transportation of these injuries without proper support is extremely hazardous.

When the neck is injured, one person kneels facing the top of the victim's head and, grasping the sides of the face and jaw between his hands, steadies the head in line with the body (Fig. 6). No pull should be made on the head, and care must be taken not to bend the neck forward. An assistant supports the legs by holding the feet. A third helper then reaches across the door or other support that has been placed beside the victim and takes a firm grasp of the clothing at hip and shoulder. At a given signal, the victim is slid sidewise onto the door. All assistants must work smoothly together so as not to twist or bend the victim's neck. Support of the head must not be relinquished once the victim has been placed on the improvised stretcher but must be maintained throughout transportation. The door, with the injured person on it, may then be lifted and placed in a truck or wagon for conveyance to a hospital.

When the back is injured and the victim lies face down, he may simply be pulled sidewise onto the door by two people working together, one grasping the feet and the other the clothes at hip and shoulder, as described above. If the victim happens to lie face up, his arms should be brought above his head, and he should be rolled slowly over on the door, which has been placed on the ground alongside him. When this is done, it is essential to keep the trunk and extremities in line so that they are moved as one piece. In this way, the victim's back is not twisted or bent, and danger to the spinal cord is avoided.

When a rigid support such as a door cannot be found, an automobile robe or blanket, if available, may be used for conveyance of the victim, as follows. If a neck fracture is suspected and the victim lies face up, the blanket, rolled tightly lengthwise for about two thirds its width, is placed alongside him with the rolled portion next to his body. One assistant steadies the head in line with the body, as before, while one or two others tuck the blanket roll carefully under the victim and gradually unroll it beneath him, little by little, working slowly and smoothly, until the victim lies on the fully opened blanket. If the person with a neck injury lies face down, the head should be steadied, the arms brought above the head, and the body then rolled slowly over on to the blanket, which has been stretched out beside him. The arms may then be brought to the sides. In this maneuver, of course, care must be exercised to keep the head, trunk and extremities in line and not allow the neck to be twisted or bent.

If the victim has a broken back and lies face up, he may be rolled over onto the open blanket in the same way as described for a rigid support.

If, however, he lies face down, he may be lifted by two assistants, one grasping him beneath the arms and the other around the thighs just above the knees, and placed gently, still face down, on the open blanket.

Once on the blanket, he may be lifted and carried between two assistants, who firmly grip the blanket on each side of the victim at the level of

FIGURE 7 Two Methods of Improvising an Emergency Stretcher with Coats or Jackets

his shoulders and the middle of the thighs. In the event of neck fracture, head support must be maintained by a third assistant throughout transportation.

It happens sometimes that not even a robe or blanket can be found. Improvisation may still be possible. If two coats or jackets are stretched out

side by side, one is buttoned to the other, and the ends of the adjacent sleeves are tied together, a suitable blanketlike support will have been made (Fig 7). Better still, if two long poles or saplings can be found, a stretcher may be improvised with the two coats as follows. The open coats are stretched out on the ground, tail to tail. Each pole is slipped through the sleeve of one coat and the corresponding sleeve of the other, and each coat is buttoned. This provides a very serviceable stretcher by which two people, grasping the ends of the poles, can transport even a heavy person.

* * *

In conclusion, physicians who are teaching first-aid classes must always bear in mind the fact that the listeners are not actual or potential physicians. Thus, too much knowledge on the layman's part is not taken for granted, simple terms and language that they are sure to understand will be used, and the scope of instruction will be restricted to matters intimately concerned with first aid for fractures. About all, one should stress the points that, whenever possible, medical assistance should immediately be summoned and that the instruction given is for the sole purpose of protecting the victim from further injury until he can receive professional care.

The foregoing suggestions have been made in the hope of lightening to some extent the burden assumed by the physician who volunteers to instruct laymen in emergency splinting. The result of personal experience in this type of instruction, these methods have been tested and found practical and effective. They are not represented as necessarily the best, certainly not the only, procedures that may be followed. But, if adopted, they will be found simple to teach and reliable in application.

THE EFFECT OF POSTOPERATIVE INTERCOSTAL-NERVE
BLOCK ON PULMONARY VENTILATION*

ARNOLD STARR, M.D.,† AND SAMUEL GILMAN, M.D.‡

BOSTON

A SIGNIFICANT decrease of pulmonary ventilation following upper abdominal incisions has been repeatedly demonstrated.^{1, 2} Figure 1A is a spirometric record obtained with a Collins metabolism apparatus on a forty-six-year-old woman breathing air. From this tracing, it may be

vertical right rectus-splitting incision: the tidal air measured 280 cc., the respiratory rate 22 per minute, the vital capacity 1400 cc., and the minute pulmonary volume 6160 cc. This represents a postoperative reduction in vital capacity of 20 per cent, and in minute pulmonary volume of 15 per

FIGURE 1. Spirometric Records before and after Choledochostomy.

calculated that the tidal air is 400 cc., the respiratory rate 18 per minute, the vital capacity 1800 cc. and the minute pulmonary volume 7200 cc. Figure 1B is a tracing from the same patient, taken in a like manner, twenty-four hours after choledochostomy had been done through a

cent. A reduction in pulmonary ventilation is the usual change following upper abdominal incisions in women. Beecher² found an even greater reduction in vital capacity in men following upper abdominal operations.

Reduced pulmonary ventilation has been ascribed to inhibition of respiratory excursion, to tight dressings, which restrict the costal margins, to splinting of the abdominal musculature resulting from pain in the wound, and to decreased diaphragmatic excursion caused by intestinal dis-

tion. Expansion of the lower lobes of the lungs follows closely the movements of the sixth, seventh, eighth, ninth and tenth ribs and their attached muscles. The diaphragm is the dominant organ in facilitating ventilation of the lower lobes, as Keith⁸ has shown. The lower sets of ribs are especially adapted to act with the diaphragm and are an intrinsic part of the diaphragmatic mechanism. Since the oblique abdominal muscles are antagonists to the diaphragm, the spasm induced in them by upper abdominal incision prevents full excursion of the diaphragm as well as of the lower ribs. These factors are involved in the interference with normal pul-

monary ventilation of relief of the postoperative wound pain of upper abdominal incisions. Spirometric tracings were made twenty-four hours postoperatively before and after intercostal anesthesia. The Bartlett technic was used. The sixth to the tenth intercostal nerves of 8 patients who had had operations on the biliary tract were injected in the mid-

logical.

monary ventilation and, presumably, are the basis for the occurrence of postoperative pulmonary complications, especially in the lower lobes.

Relief from pain in upper abdominal incisions, by relaxing the reflex spasm of the somatic musculature involved, should therefore improve pulmonary ventilation. Capelle⁹ relieved painful spasm in the wound by continuous novocain infusion and reported a resulting improved vital capacity and thoracic excursion. This procedure is impracticable because of the danger of toxicity from the continued administration of the anesthetic as well as interference with wound healing. Collins⁵ found an increase in vital capacity following infiltration of the wound with an aqueous solution of Eucupin and novocain. Zollinger⁶ injected an almond oil solution of Eucupin base, ethylaminobenzoate and benzyl alcohol into the intercostal nerves of 15 patients who had had upper abdominal operations. By comparing the resulting average vital capacity with the postoperative average determined previously by Cutler and Hoer,⁷ he concluded that the decreased pain of upper abdominal incisions following intercostal-nerve block increased vital capacity. On the basis of 2 favorable cases, Gius⁸ recommended paravertebral novocain injection into the intercostal nerves for the improvement of respiratory function in patients

axillary line on the right side to desensitize the upper abdominal wall without affecting the intercostal muscles, whose nerve supply leaves the main intercostal trunk posterior to the midaxillary region.

The anesthetic solution used in this study was 0.2 per cent Eucupindihydrochloride and 1 per cent procaine hydrochloride in Ringer's solution. Although this solution had been used in patients by Collins, its possible damaging effect on various tissues and cavities was first tested by us in rabbits, and no harmful effect was observed. Following intercostal nerve block, anesthesia persisted for three or four hours, and analgesia remained for more than twenty-four hours, when abdominal pain returned, it was mild in every case. Longer acting agents, such as oily solutions of anesthetic substances, might be more desirable, but since Duncan¹⁰ observed serious degeneration in the motor nerves of the cat following the use of these anesthetic mixtures, they should be applied with caution.

Table 1 summarizes the data on pulmonary ventilation in a group of respiratory tracings obtained before and after intercostal nerve block twenty-four hours after an upper abdominal procedure. Following relief of upper abdominal wound pain by intercostal nerve block, the respiratory rate shows

no constant change; in 3 cases, the rate was decreased, in 2 it was increased, and in 3 it was not altered. The tidal air likewise showed no consistent change: in 1 case it was decreased, in 3 it was increased, and in 4 it was unchanged. The vital capacity showed a moderate increase in 7 of the 8 cases following relief of wound pain. In Case 8, the block was only partially effective, and there was some gastric dilatation, which may account for the lack of increase in vital capacity. The average increase of vital capacity in this group of cases was 23 per cent. The minute pulmonary volume showed no constant change, as one might expect, since the respiratory rate and tidal air were not altered in any constant direction.

Although the increase in vital capacity following relief of wound pain by intercostal-nerve block was of itself significant, other benefits were noted. The patients moved about more readily. Coughing was not only easier but also more effective. In 1 striking case, a patient who had high fever, rapid pulse and evidence of consolidation at the lung bases for forty-eight hours after epigastric herniorrhaphy obtained rapid relief of pulmonary signs and symptoms and became afebrile twelve hours after intercostal-nerve block, which effectively relieved the wound pain. This improvement was almost certainly due to the facts that cough became

easier and that the patient was able to raise a large quantity of thick sputum. Although relief might have occurred in spite of nerve block, the patient's immediate appreciation of increased comfort in breathing and in coughing was very definite.

CONCLUSION

The relief of upper-abdominal-wound pain by intercostal-nerve block improves the vital capacity and benefits the patient in other respects. The procedure is therefore worthy of more frequent application.

MEDICAL PROGRESS

ARTERIAL HYPERTENSION*

ROBERT W. WILKINS, M.D.†

BOSTON

IN the last two years, a tremendous amount of work has been done in an attempt to solve the problems of arterial hypertension. Although much has been learned concerning the mechanisms of the renal types of hypertension produced experimentally in animals, and also of their clinical counterparts occurring naturally in man, little of practical value has been added to the methods of preventing or relieving the disease in human beings.

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4 00).

*From the Robert Dawson Evans Memorial, Massachusetts Memorial Hospitals, Boston, and the Department of Medicine, Boston University School of Medicine.

Presented in part at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1942.

HYPERTENSION OF RENAL ORIGIN

Animal Experiments

Pathologic physiology. It seems clear that the arterial hypertension produced in animals by interference with the blood supply of a kidney^{1, 2} is due to the increased pressor activity of the blood leaving that kidney (Fig. 1).³⁻⁶ Furthermore, it appears that this hypertension may be moderated by the presence of a normal kidney,^{7, 8} which can reduce the pressor properties of blood that has passed through the so-called "ischemic" kidney.⁶ Although the procedures used to produce this type of hypertension may be severe enough actually to reduce the blood flow through the kidney, they may be so nicely adjusted that they are exactly balanced by the ensuing responses in renal hemodynamics and systemic arterial pressure, and thus result in no significant change in renal blood flow.^{9, 10}

Strictly speaking, therefore, it may be inaccurate to apply the term, "renal ischemia," to the circulatory disturbance produced in the kidney. It has been shown that the reduction of arterial pulse pressure within the kidney is probably the abnormality that initiates and maintains the renal type of experimental hypertension.¹¹

The hypertension produced in animals by clamping of the aorta just above the renal arteries (simulating coarctation) seems to be of the renal

FIGURE 1 Diagram of the Probable Mechanism of Renal ('Ischemic') Hypertension

The blood (circles), on passing through the ischemic kidney (with a clamp on the artery), acquires increased pressor (+) activity but, after passing through a normal kidney, loses some of this activity

type.^{6 12 13} Intermittent occlusion of the renal artery, up to thirty minutes daily, does not cause a persistent elevation of arterial pressure,¹⁴ although there may be a brief rise of pressure immediately after the release of the occlusion.¹⁵⁻¹⁷

In animals with renal hypertension, more refined methods of measuring renal hemodynamics^{18 19} have revealed evidence of vasoconstriction of the efferent arterioles of the glomeruli (Fig 2).^{6 10 20}

FIGURE 2 Diagram of a Glomerulus, Showing Constriction of Efferent Arteriole

This efferent arteriole constriction within the kidney itself is apparently part of the generalized vasoconstrictor response to the humoral pressor material elaborated by the ischemic kidney

Searches for the humoral pressor substance believed to be responsible for renal hypertension have proceeded in two directions: study of extracts of kidney, and study of hypertensive blood.

From the renal cortex, a protein extract may be obtained that, when injected intravenously into intact animals, produces hypertension similar to renal hypertension. Actually, this extract, renin,²¹ is not itself a pressor agent, but reacts with a pseudoglobulin fraction of blood (called "renin activator,"²² or "hypertensin precursor,"²³) to form a strongly pressor substance, called "angiotonin,"²⁴ or "hypertensin,"²⁵ which, when injected intravenously, causes arterial hypertension and vasoconstriction generally,²⁶ including the efferent arterioles of the glomeruli.²⁷

Studies of the renal and peripheral venous blood of animals with renal hypertension have shown it to be more vasoconstrictor and vasopressor than normal.^{5 6 23 28 29} Treated chemically, such blood may yield material similar to renin, and to angiotonin or hypertensin. In addition, it may exhibit other properties differing from those of renin or angiotonin.^{6 30 31} However, the increased pressor activity of hypertensive blood has yet to be identified with the presence of one or more specific chemical compounds in abnormal amounts. That a whole series of such compounds is at least theoretically possible is indicated by the observations that similar substances are formed by the action of pepsin on renin activator (hypertensin precursor)^{32 33} and of anoxic kidney tissue (decarboxylating enzymes) on amino acids.³⁴

Treatment. It was shown early that experimental hypertension due to unilateral renal ischemia could be relieved by removal of the involved kidney.³ This fact settled a very important question, namely, whether hypertension is necessarily an irreversible state. The demonstration that renal hypertension, at least early in its course, is a functional disease, capable of relief, gave a hopeful outlook. This line of work has been extended, however, to demonstrate that, if a severe hypertension is allowed to persist, hypertensive vascular lesions may appear in widespread areas, including the presumably normal kidney.³⁵⁻³⁷ Furthermore, removal of the ischemic kidney at this stage may be followed not by complete relief but by a residual hypertension.^{36 38} Thus, it appears that a vicious circle may be established in which the hypertension due to impairment of renal circulation may produce lesions that cause further impairment and, as a result, more hypertension (Fig 3). The occurrence of malignant hypertension may be due to such a mechanism.³⁶

Since it was established that the normal kidney is able to decrease the pressor activity of renal hy

pertensive blood, it was logical to search for a neutralizing or antipressor substance in the kidney. Renal extracts have been obtained that lower the arterial pressure of hypertensive but not of normal animals,³⁹⁻⁴¹ and decrease efferent arteriolar constriction.⁴² They also neutralize the effects of angiotonin.^{42, 43} Similar results have been obtained with tyrosinase⁴⁴ and amineoxidase,^{45, 46} which were used with the idea of destroying whole groups of pressor substances, if present. Unfortunately, these depressor materials have not yet been freed of toxic and pyrogenic properties, especially when given parenterally. Therefore, caution must be used in attributing their depressor action to the

FIGURE 3. *Diagram of the Vicious Circle in Renal Hypertension.*

presence of specific neutralizing substances, since it has been shown that various nonspecific vasodilating or pyrogenic materials may have similar effects.^{47, 48}

Clinical Application in Human Beings

Parallel observations have been made in human beings confirming almost every important point learned about renal hypertension in experimental animals. Many cases of so-called "renal hypertension" in man have been reported,⁴⁹⁻⁵¹ including a number that have been relieved by removal of a unilaterally involved kidney.⁵⁰⁻⁵⁵ In children, such cases have been particularly dramatic.⁵⁶⁻⁵⁹

Studies of the renal hemodynamics in hypertensive patients have revealed evidence of efferent arteriolar constriction in the kidneys.^{48, 60} In those whose arterial pressure has been lowered following the removal of a diseased kidney, the efferent arteriolar constriction in the remaining kidney has been found to decrease.⁶¹ The total renal blood flow in unselected hypertensive patients is usually below normal.^{48, 60} However, differential function tests of the two kidneys in such patients have failed to reveal unilateral renal ischemia as a frequent finding in essential hypertension.⁶²

Clinical⁶³ and pathological^{53, 64} studies of cases of renal hypertension not relieved, or only partially relieved, by nephrectomy support the view that hypertension of some duration is accompanied by the development of hypertensive vascular

lesions, which may involve the normal kidney and thus produce a vicious circle (Fig. 3).^{36, 65} Structural changes have been found in the arterioles of muscles after renal hypertension of only a few months' duration.⁶⁶ Such lesions are indistinguishable from those found in essential hypertension.

Patients with coarctation of the aorta have been shown to have generalized diastolic hypertension,⁶⁷ and also efferent renal arteriolar constriction.⁶⁸ These observations are in accord with experimental studies suggesting that the arterial hypertension associated with coarctation is renal in origin.

The effects of renin,⁶⁹ angiotonin⁷⁰⁻⁷² and hypertensin⁷³ have been studied in human beings. Injected intravenously, these substances produce elevations of arterial pressure roughly proportional to the dosage used. The resultant hypertension is similar in many ways to clinical essential hypertension, but differs from it in certain respects, particularly in being accompanied by a considerable rise in venous pressure. Angiotonin produces efferent arteriolar constriction in normal human kidneys.^{20, 48, 72}

The use of depressor substances in the treatment of patients with hypertension has been restricted by the scarcity of the materials, and also by the toxic side reactions produced by certain preparations. In some patients, depressor renal extracts are said to lower the arterial pressure, decrease the efferent arteriolar constriction, and relieve the symptoms, especially headache and impairment of vision.^{30, 42} However, the effects are not consistent, and are complicated by the unpredictable variations of the disease, as well as by the occurrence of toxic reactions. Until standard preparations can be produced in adequate amounts for general trial, the value of such depressor substances cannot be finally determined.

NEUROGENIC HYPERTENSION

Hypertension of sympathetic nervous origin produced in animals by section of the moderator nerves^{74, 75} does not require the presence of the kidneys.⁷⁶ Hypertension due to increasing the intracranial pressure of animals apparently depends on reflex sympathetic stimulation of the heart, either directly through the cardiac nerves or indirectly through the mediation of the adrenal glands.⁷⁷

The role of the sympathetic nervous system in human hypertension remains obscure. Elevations of arterial pressure, especially in response to unpleasant stimuli, presumably occur in both normal and hypertensive persons through the mediation of the sympathetic nervous system. However, there is no direct relation between the amount of the

rise in arterial pressure and the degree of sympathetic vasoconstriction in the skin,⁷⁸ or in the muscular parts of the extremities⁷⁹ during such stimuli. Neither is there a loss of the pressor response after extensive splanchnic sympathectomy.⁸⁰⁻⁸¹ As yet, the sympathetic nervous mechanism in such responses is not clear. It appears that excessive responses (hyper-reactions) are commoner among hypertensive and prehypertensive patients than among persons who never develop hypertension.⁸² In fact, it seems that a tendency to abnormal elevations of arterial pressure is more important than the presence of renal disease in determining the subsequent development of sustained hypertension.⁸³ However, it should be noted that some hypertensive, hyper-reactive patients who have been relieved of their hypertension by the removal of an ischemic kidney have also been relieved of their hyper-reactivity.⁸⁴

A recent progress report⁸⁵ has summarized the knowledge to date concerning surgery of the autonomic nervous system in man. In some patients with essential hypertension, extensive sympathectomy definitely lowers the arterial pressure, especially with the patient in the upright position. It apparently does not increase the renal blood flow or decrease the efferent arteriolar constriction.⁸⁶⁻⁸⁸ Nor does it increase the blood flow in the calf.⁷⁹⁻⁸⁰ Sympathectomy, therefore, appears to be more a symptomatic than a specific form of therapy for hypertension. However, one may argue that lowering arterial pressure by any means impedes the development of hypertensive vascular lesions, especially in the kidneys, that might establish a vicious circle. Further long term studies⁸⁹ of the patients already operated on should eventually answer the question of whether sufficient, lasting beneficial results are obtained with surgical sympathectomy to warrant its use in arterial hypertension.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28301

PRESENTATION OF CASE

A fifteen-year-old schoolboy was admitted to the hospital because of headache and swelling and redness of the face of two days' duration.

For about four months prior to entry, the patient had frequent colds with considerable nasal discharge and postnasal drip. Four days before entry, the patient went swimming in a pool for the first time in several weeks. Two days later he developed a cold associated with severe right frontal headache. The next day the temperature ranged from 101 to 102°F. His headache persisted, and there was swelling of his right periorbital region to such an extent that he could not see out of the right eye. He had no chills, earache or sore throat.

The past and family histories were noncontributory. A year before entry, the patient had had an attack of frontal sinusitis.

On admission, the patient appeared acutely ill. The right eye was partially closed by swelling of the orbital tissues. There was tenderness over the right frontal sinus, with accompanying swelling and redness. Upward gaze was painful. Both frontal sinuses transilluminated poorly. Physical examination was otherwise negative.

The blood pressure was 140 systolic, 80 diastolic. The temperature was 99.4°F., the pulse 72, and the respirations 17.

Examination of the blood showed a white-cell count of 22,200 with 89 per cent polymorphonuclears, and a red-cell count of 4,690,000 with 15.3 gm. hemoglobin. The urine was normal.

Röntgenograms of the sinuses showed gross thickening of the mucous membrane of the right antrum, with polypoid changes; the sinuses were otherwise clear.

On the third hospital day, the temperature rose to 103°F. and the patient had a series of convulsive seizures in which the head and eyes turned toward the right and then generalized convulsive movements appeared, which were more marked in the right arm and leg than in those on the left. Between seizures, the patient was stuporous and showed right hemiparesis, with extensor plantar

response on the right, and marked stiffness of the neck. A lumbar puncture gave clear colorless fluid under an initial pressure of 230 mm. of water; the fluid contained 12 polymorphonuclears, 7 lymphocytes and 2 large mononuclears per cubic millimeter. The total protein was 58 mg. per 100 cc., the sugar 103 mg., the chlorides 690 mg., and the gold-sol curve 0012311000.

The seizures increased in frequency until they occurred about every five minutes. The patient was taken to the operating room, but because of severe respiratory difficulty, operation was deferred. The convulsions were controlled by ether anesthesia. Sulfapyridine and heparin were administered. The patient regained consciousness, but had right hemiplegia and aphasia. Two days later, the headache increased and the patient became less responsive. *Staphylococcus albus* was obtained from a blood culture taken on the second hospital day. On the sixth hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS C. GRANT*: We have here a child with obvious infection of the frontal sinuses, predominantly on the right side. On the third hospital day, a critical change in his condition developed, with an increase in temperature and convulsive seizures, which began with turning of the head and eyes to the right. These convulsive seizures were much more marked in the right arm and leg than in those on the left, whereas it was the right frontal sinus that was involved. He was stuporous and had a right hemiparesis and a Babinski sign on the right. The convulsive attacks were finally controlled, and the patient regained consciousness but had a right hemiplegia and aphasia. I presume that he was right handed.

DR. CHARLES S. KUBIK: Yes.

DR. GRANT: He must obviously have had a lesion of some type in the left cerebral hemisphere, with the possibility, of course, that, since this was an infectious process and since the sinuses were involved, there might have been multiple infectious processes.

I see nothing here about the eye grounds.

DR. KUBIK: They were normal.

DR. GRANT: I suppose he was too stuporous at any time to observe the visual fields.

DR. KUBIK: No; they were normal. He was not too stuporous for that at times.

DR. GRANT: There is nothing here about the conjunctiva of the right eye. Was that inflamed, and was there any ecchymosis?

DR. KUBIK: There was no ecchymosis, but quite a bit of edema.

*Professor of neurosurgery, University of Pennsylvania Medical School.

DR. GRANT: There was pain on upward movement of the eye, but apparently no difficulty in the movement of the eye.

DR. KUBIK: No; and no diplopia.

DR. GRANT: Are any x-ray films available?

DR. KUBIK: No; the x-ray films cannot be found.

DR. GRANT: Of course in a child of this age, one would not expect to find calcification of the pineal gland, but one might pick up calcification in the choroid plexus, and any change in its position might be of significance.

It seems to me that there are two possibilities. In the first place, we have the story that, four months prior to entry, the patient had frequent colds, nasal discharge and postnasal drip. Then he had this acute crisis, with infection of the sinuses, and *probably a blood-stream infection, because of the finding of Staphylococcus albus in the blood.* My suspicion is that the acute frontal sinusitis may not have been the important factor, but only a part of the picture that drove him into the hospital. He might conceivably have had a lesion resulting from the earlier infection, such as an abscess well forward in the left frontal area, that preceded the development of the right frontal sinusitis. The convulsive attacks are certainly suggestive of a left-sided lesion, although convulsive seizures are not a common occurrence in a subcortical abscess. It is quite conceivable that he had thrombosis of the longitudinal sinus. I imagine that this thought occurred to someone else, because the patient was given heparin during his hospital stay.

Am I allowed to elaborate on the way this case should have been handled, on the sixth hospital day, when an operation was performed?

DR. TRACY B. MALLORY: Yes.

DR. GRANT: Presuming that the patient's situation had improved and that the condition for which the heparin and sulfapyridine had been given had cleared up, I should have tapped the ventricles. If, as I suspect, the right ventricle was found to be larger than the left, I should have taken this as evidence of a lesion in the left frontal area and tapped there, expecting to find pus either on the surface or in the brain.

A PHYSICIAN: Is it likely that he had osteomyelitis?

DR. KUBIK: X-ray films taken with that in mind did not show an osteomyelitis.

A PHYSICIAN: Would you consider a subdural empyema?

DR. GRANT: I considered it, and I presume, if present, it would have been in the left temporal region, where it would possibly be picked up when one tapped for abscess.

DR. JAMES C. WHITE: Would you wait for the x-ray films to be positive before making a diagnosis of osteomyelitis?

DR. GRANT: No, I should not wait for them. I am presuming the physicians in charge nursed the patient for the respiratory difficulty he was in, and considered that if he ever was going to be operated on, he should be operated on then.

A PHYSICIAN: Do you think he had a right orbital abscess?

DR. GRANT: They did not do anything about it if he had. I take it that the orbital swelling disappeared. Did it disappear?

DR. KUBIK: No, it did not disappear; but it did not get any worse, and the patient was not operated on for orbital abscess.

A PHYSICIAN: Why do you lean to temporal-lobe abscess instead of frontal?

DR. GRANT: I am presuming that the boy had some difficulty with speech. They state that aphasia developed. I do not believe one can tell whether the effect of the lesion on the speech center was from in front or from behind or whether it lay directly in the speech center. I think we have to presume that the infection started in the sinuses in front. The lesion is more likely to be fronto-temporal than temporoparietal.

DR. WILDER PENFIELD: How can you tell irregularity of the ventricles?

DR. GRANT: You can find the difference in size between them by the amount of fluid withdrawn from each of them.

DR. PENFIELD: I wish I could.

A PHYSICIAN: Why do you object to putting air in?

DR. GRANT: I think this child was too sick. A ventricular estimation is sufficient.

A PHYSICIAN: Would you consider the injection of Thorotrast?

DR. GRANT: No, I think this boy was too sick. He had been carried through a respiratory collapse. The respiratory collapse is commoner with a cerebellar than with a frontal lesion. I do not have any data here regarding what immediately preceded the severe respiratory difficulty. Was there an accompanying drop in pulse, or was it purely respiratory? Was it due to positional change on the operating table or to the administration of anesthesia?

DR. KUBIK: It occurred before the anesthesia was started. He began to have seizures, almost constantly, and then stopped breathing. They telephoned from the operating room, as a matter of fact, that the patient had died.

A PHYSICIAN: Is there any relation between the trouble and the spinal puncture?

DR. GRANT. I should presume that they would not remove any amount of fluid—just a drop or two to get the cell count.

A PHYSICIAN: They did the total protein and chloride.

DR. GRANT: That requires about 8 cc. I should not have done that. The record does not state what the sequence was. It may have been done some time before.

A PHYSICIAN: The convulsions were very frequent for an abscess, were they not?

DR. GRANT: Yes; my conception about this boy is that he had a frontal abscess before the acute symptoms developed. Then sinus thrombosis produced cortical infection, irritation and convulsions.

A PHYSICIAN: Would you consider that the aphasia and hemiplegia were purely postconvulsive?

DR. GRANT: No, because they came on, as I gather, late. I think you are correct in presuming they might have been. It simply says that the patient regained consciousness, then had aphasia and right hemiplegia.

A PHYSICIAN: What is wrong with the diagnosis of acute early encephalitis deep in the frontal lobe?

DR. GRANT: The cell count was not particularly suggestive of encephalitis. It was not high enough, nor do I believe that the cells would have been predominantly polymorphonuclears. It looks more like abscess.

CLINICAL DIAGNOSIS

Subdural abscess, left motor area.

DR. GRANT'S DIAGNOSES

Left frontal abscess.

Subcortical longitudinal sinus thrombosis, spreading to veins over left cortex and producing patchy meningitis and convulsive seizures.

ANATOMICAL DIAGNOSES

Subdural empyema.

Thrombophlebitis of superior longitudinal sinus.

Frontal sinusitis.

Frontal osteomyelitis.

DR. KUBIK: This patient was sent up to the operating room the first time with a diagnosis of subdural abscess, but because of the respiratory difficulty, the operation was postponed. The seizures were controlled with ether. He regained consciousness, but the hemiplegia and aphasia persisted. Three days later, he became worse, and a left subdural empyema was drained through a lateral frontal burr hole. The patient had a very stormy convalescence, with a number of convulsive seizures, but he finally pulled through and recovered

completely from the aphasia and hemiplegia. In the two years following his illness, he has had three or four seizures, and he is now taking dilantin. There was no x-ray evidence of osteomyelitis at the time of operation or for two or three weeks after that. Then we stopped taking x-ray films, and he was discharged after about seven weeks. Two weeks later, he came back with frontal osteomyelitis, demonstrated by x-ray study. This was operated on, and at the operation, the superior longitudinal sinus was found to be thrombosed. It seems likely that the thrombophlebitis preceded and was responsible for the subdural injection.

CASE 28302

PRESENTATION OF CASE

A fifty-five-year-old Canadian toolmaker was admitted to the hospital because of nausea, diplopia, vertigo, headache and spells of unconsciousness and disorientation occurring over a period of at least six weeks.

The patient had suffered from "migraine headaches" most of his life. These appeared about once a month and were accompanied by scotomas, nausea and vomiting. Four years before entry, the patient was in an automobile accident. He struck the left side of his head and was unconscious for a few minutes. Subsequently, there was insidious appearance of irritability, lack of judgment, memory loss and disorientation. These personality changes became progressively more marked. One year before entry, the usual headaches changed character, becoming occipital, with pounding radiation to both frontal regions and associated nausea, vomiting and vertigo. Eight months before entry cholecystectomy was performed at a community hospital; "stones" were found. Six weeks before entry, there was marked increase in the nausea and vomiting that accompanied the headaches. The patient went to a community hospital, where "an old duodenal ulcer" was demonstrated roentgenographically; treatment by the Sippy diet afforded no relief. After three weeks, the patient was transferred to another community hospital. The headaches continued as before, and the patient suddenly became comatose during the course of one. A lumbar puncture showed an initial spinal fluid pressure equivalent to between 350 and 375 mm. of water. His pulse rose from 40 to 100 following the puncture, and there was temporary relief of symptoms. He was then transferred to this hospital.

On admission the patient was disoriented, vomiting and complaining of dizziness and double vision. There was evidence of recent weight loss and dehydration. The heart, lungs and abdomen

seemed normal. The neck was stiff, and there was a Kernig sign. The pupils were unequal, alternately enlarging and contracting. The optic disks were normal. There were questionable hypesthesia and hypalgesia in the left trigeminal-nerve field. The musculature of the trunk and extremities was generally wasted and flaccid, possibly more so on the left than on the right. The tendon reflexes were hypoactive and equal.

The blood pressure was 120 systolic, 80 diastolic. The temperature was 99°F., the pulse 44, and the respirations 15.

Examination of the blood showed a white-cell count of 16,700 with 71 per cent polymorphonuclears, and a red-cell count of 4,900,000 with 85 per cent hemoglobin. The urine showed a ++ test for albumin.

Roentgenograms of the skull showed no abnormalities. A roentgenogram of the chest showed only a few small areas of calcification in the right lung.

The patient became increasingly stuporous. On the second hospital day, bilateral occipital burr holes were made, under local anesthesia. Clear colorless fluid was obtained from both ventricles. The pressure was considerably increased, particularly on the left. The fluid from the left ventricle showed 34 polymorphonuclears and 12 lymphocytes per cubic millimeter with a total protein of 36 mg. per 100 cc. The fluid from the right ventricle showed 62 polymorphonuclears and 28 lymphocytes per cubic millimeter with a total protein of 44 mg. per 100 cc. The gold-sol curve was 0001210000, and the Wassermann reaction was negative.

Following the tap, the patient seemed improved. Adequate hydration was obtained by vigorous intravenous therapy. Ventricular tap was repeated on the second night in the hospital because of the return of drowsiness, disorientation and a slow pulse, with spasticity of the left arm and leg. Twelve cubic centimeters of orange fluid was aspirated, with improvement in the patient's condition. During the next few days, much restlessness necessitated paraldehyde sedation. A right hemiparesis appeared. An electroencephalogram suggested "electrical pathology" in the right frontal lobe. A ventriculogram performed on the third hospital day showed slight dilatation of the lateral ventricles, more marked on the left, and slight widening of the third ventricle; the surface filling showed some widening of the sulci. No tumor was demonstrable. On the eighth hospital day, bilateral temporal burr holes were made under local anesthesia, and the subdural space was explored without significant findings. Subsequent

lumbar punctures gave xanthochromic fluid, with an initial pressure of 440 mm.

The patient remained restless and unco-operative, constantly pulling off his dressings. Ultimately the left occipital burr hole became septic. On the twenty-third hospital day, the temperature rose to 104°F., and there was patchy bronchial breathing, with moist rales at the base. Sulfapyridine was given, but death occurred on the following day.

DIFFERENTIAL DIAGNOSIS

DR. JOST MICHELSEN: This is a very complex story, but one conclusion seems to be fairly safe: shortly before and on admission to the hospital this patient had an intracranial lesion that produced an elevation of intracranial pressure. The findings on lumbar puncture in the outside hospital and on ventricular examination in this hospital bear out that point. Additional evidence can be derived from the facts that, following the lumbar puncture, the pulse rose from the very slow rate (40) to 100 beats per minute and that there was temporary relief of symptoms. In view of these findings and observations, the absence of papilledema is of little significance.

The questions arise, Where in the cranial cavity was this lesion localized, and what type of lesion did this patient have? Let us start with the findings on admission. The patient complained of double vision. We do not know which eye muscles or nerves were involved. Weakness of the sixth, as well as of the third, nerve can be interpreted as general signs of pressure. The pupils were unequal, and there was a hippus. Perhaps these signs, together with the rigidity of the neck and Kernig sign, suggest that there was a tentorial pressure cone, which produced compression of the midbrain. Hypesthesia and hypalgesia of the left trigeminal field may be caused by a lesion anywhere in the course of the trigeminal nerve from the gasserian ganglion to the pons. The flaccidity of all muscles and corresponding sluggishness of the tendon reflexes do not mean very much if we consider the poor general condition of the patient on admission. Later, spasticity of the left arm and leg developed, apparently without weakness. I wonder if the observer made a distinction between spasticity and rigidity. If the change of muscle tension involves both the flexor and extensor muscles, it should be called "rigidity," but if the antigravity muscles are chiefly involved, the condition should be designated by the term "spasticity." Rigidity is found clinically in diseases of the extrapyramidal system; spasticity arises from lesions of the pyramidal system below the level of the cortex or, if of the

cortex itself, from combined involvement of the motor area and the extrapyramidal area.

During the next few days, right hemiparesis appeared. This time the state of the involved muscles is not given. Nor is it mentioned whether the patient became aphasic. Was he right handed or left handed? The electroencephalogram indicated "pathology" in the right frontal lobe. X-ray films of the skull were normal, and hence the pineal gland was in the midline; and the ventriculogram failed to demonstrate a shift or filling defect of the ventricular system. Consequently, we must assume, contrary to the localization by the electroencephalogram, that the process was a diffuse one and certainly not limited to one hemisphere of the brain.

The question of the type of lesion is not less involved. A brain tumor can be ruled out. The absence of changes in the ventriculogram is not compatible with such widespread involvement by tumor. There is no evidence of a primary focus to indicate multiple metastases to the brain: the albumin in the urine is not sufficient evidence, and no other changes of the urinary tract are reported.

Thus, there remain to be considered subacute or chronic, vascular or inflammatory lesions. I say subacute or chronic lesions because it is difficult to determine from the history when this fatal disease started.

The patient had suffered from headaches most of his life. Their periodic occurrence and association with scotomas, nausea and vomiting are indeed suggestive of migraine, but it must be kept in mind that there are other conditions with constant organic pathology that give rise to similar perineuric manifestations first, and reveal their true character later. The commonest lesions of this type are hemangiomas of or near the occipital lobe. This possibility, however, is remote, because a hemangioma should have been shown in the ventriculogram.

The next point that must be settled is the possible relation of the head injury to the lesion that resulted in this man's death. Following the injury, he developed symptoms such as irritability, lack of judgment, memory loss and disorientation. The underlying pathology of such a postconcussional syndrome may be widespread physical damage to the brain, and I assume that the asymmetrical dilatation of the lateral ventricles and the widening of the third ventricle, as well as of the sulci, demonstrate objectively this pathology in the form of atrophy of the brain. But this alone did not account for the signs that the patient developed in the last stage of his disease. He may have had a subdural hematoma in addition to the other damage to his brain. This is a good possibility. The delayed onset of symptoms in subdural hematomas is not unusual, and the clinical picture is so varia-

ble that often the diagnosis cannot be made without trephine exploration. Such exploration was carried out on the eighth hospital day, without significant findings. It seems to me that it should have preceded the other operations. One can assume, however, that the patient did not have a subdural hematoma; furthermore, the ventricular puncture performed as the first procedure on the second hospital day yielded valuable information. There was an increase of cells and protein in the ventricular fluid. I am unable to evaluate the difference in pressure, cells and protein on the two sides, but the presence of white cells and the increase of protein in the ventricular fluid are very suggestive of an intracranial infection. Occasionally, brain tumor close to the ventricular system produces similar changes, but brain tumor has been ruled out.

It is unfortunate that the examination of the cerebrospinal fluid obtained in the outside hospital was incomplete, and it is equally unfortunate that the lumbar puncture was not repeated after his admission here, in spite of the beneficial results of the first lumbar tap. I should like to know about the cell count, the sugar, the chlorides and the findings on bacterial examination of the spinal fluid. The examination of the ventricular fluid apparently was also incomplete. The negative Wassermann reaction, however, eliminates a syphilitic infection.

Because of the lack of adequate information concerning the cerebrospinal fluid, the analysis from now on must be based more or less on guesswork. The trauma was not such as to suggest the development of an intracranial abscess or multiple abscesses. There was no evidence of an external compound fracture or cerebrospinal-fluid leak, and there was no other focus from which they could have originated. Did this man have an encephalitis? In reviewing the clinical findings once more, one wonders if rigidity of the neck and the Kernig as well as the other signs were not produced by the intracranial infection rather than by a pressure cone; in addition, signs of meningeal irritation are rare in encephalitis. Tuberculous meningitis may be considered. The negative chest plate does not rule it out. The temperature in tuberculous meningitis is often markedly irregular, which may explain the absence of any elevation in the beginning. A fungous infection of the central nervous system may be quite consistent with the course of the disease in this man. Metastatic carcinomatosis of the meninges is unlikely since, as previously mentioned, no primary focus was found. There is no evidence that the patient had a meningitis originating from the ears or sinuses, which apparently were normal. There was no osteomyelitis of the skull or any other source

from which an infection of the venous system of the brain may have originated. Furthermore, no definite relation can be established between the intracranial process and the abdominal lesions.

In summary, I should say that the patient suffered from migraine, gallstones and a duodenal ulcer. The head injury produced atrophy of the brain. In addition to these changes, the patient had widespread intracranial disease, with increased intracranial pressure and irritation or infection of the meninges. Brain tumor is ruled out. Single or multiple intracranial abscesses are considered unlikely. Metastatic involvement of the brain and meninges is eliminated. Tuberculous and Torula meningitides, as well as encephalitis and other forms of meningitis and thrombophlebitis, are unlikely. In other words, a definite differential diagnosis of the intracranial process in the final stage is impossible. There were terminal bronchopneumonia and wound sepsis.

CLINICAL DIAGNOSES

Encephalitis (type undetermined).
Cerebral atrophy.
Terminal bronchopneumonia.

DR. MICHELSEN'S DIAGNOSES

Migraine.
Gallstones.
Duodenal ulcer.
Widespread intracranial disease (meningitis? encephalitis?).
Terminal bronchopneumonia.
Wound sepsis.

ANATOMICAL DIAGNOSES

Carcinoma of stomach, with metastases to meninges, brain and left adrenal gland.
Operative wounds: bilateral burr holes, occipital and temporal; cholecystectomy; and appendectomy.
Subdural abscess, postoperative.
Lateral-sinus thrombosis, acute.
Congenital anomaly: extreme hypoplasia of left kidney, with ureter draining into seminal vesicle.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This patient puzzled the clinicians in charge of this case on the ward quite as much as it has Dr. Michelsen. They were never willing to commit themselves to a definite diagnosis. When the patient first came in there seemed to be a slight though remote chance of subdural hematoma, and the original burr holes were made primarily with the purpose of ruling out this one potentially remediable condition. When nothing was found, the impression shifted somewhat in favor of encephalitis, which was the final diagnosis on the death report.

At autopsy, obvious sepsis of the operative wound was found, which had extended through one of the burr holes to produce a localized subdural abscess. There was also a fresh, nonocclusive thrombosis of the lateral sinus. The meninges elsewhere over the cortex showed injection, and thickening and opacity of the arachnoid were also present. It was assumed that this represented a rather chronic meningitis. In the rest of the examination, numerous lesions were found that did not seem to have any connection with the cerebral process. There was a healed ulcer of the duodenum, and a second, still active, ulcer in the prepyloric area of the stomach. The gall bladder had been removed, and there was some dilatation of the common bile duct and hepatic duct. There were anomalies of the urinary tract. The left kidney could not be identified. The left ureter was completely atretic and emptied into the left seminal vesicle instead of entering the bladder at the trigone. The right kidney showed compensatory hypertrophy. A small tumor nodule was found in the medulla of the left adrenal gland. When the microscopic sections came through, it was at once apparent that the thickened arachnoid was diffusely infiltrated with tumor cells, some of which had a characteristic signet-ring appearance. Examination of the prepyloric ulcer showed its margins to be frankly carcinomatous, and the nodule in the adrenal gland also proved to be a metastasis. Although no gross metastases could be found within the cerebral substance, numerous minute foci of tumor cells were found on microscopic observation.

SUBDURAL HEMATOMAS

THE formation and organization of a blood clot beneath the dura covering the brain, either completely composed of blood or partly mixed with cerebrospinal fluid, has long been recognized as a serious sequela of cerebral trauma, or as an occasional accompaniment of the blood dyscrasias and scurvy. A clear pathological concept of subdural hematomas, an understanding of how commonly the lesion may be found if constantly kept in mind by the clinician and an appreciation of the favorable influence of surgical treatment, when applied early, have been arrived at only in comparatively recent times. In 1933 and 1934, many erroneous ideas concerning subdural hematomas were erased from the record by Leary and his associates, and it is to

him that we are indebted for our modern concept of this disease. His work, as Munro points out in this issue of the *Journal*, is both "fundamental and unquestionably accurate." Thanks to Leary and subsequent investigators, these lesions can now be divided into two broad groups—the solid type and the mixed type, the latter in its common chronic stage often forming a fluid cyst, sometimes called a "hydroma" or "hygroma," a descriptive term of no particular significance.

Munro has shown that the solid type, usually thought of as the commonest of all subdural hematomas, is, in his experience as head of a large, active, neurosurgical service, the least common. The solid forms are of the nonexpanding type, some caused by trauma and others due to blood dyscrasias. They are often not diagnosed in their acute stage and only disclose themselves as fortuitous findings at autopsy in patients who, not infrequently, have become psychotic. It is this form of subdural hematoma that has received undue emphasis in textbooks and current medical thought, partly owing to the prominence given it by Putnam and Cushing in 1935. In Munro's series, it formed only 45 out of 310 verified cases. The lesions, however, are often favorably affected by surgical intervention, although the operative mortality may rise to 33 per cent, largely the result of deaths in the older age group.

The mixed forms are commoner than the solid types and are exclusively due to craniocerebral injuries. They consist of a mixture of blood and cerebrospinal fluid and expand during the course of their development. Their growth is often rapid in the first five weeks after injury and then somewhat slower for the subsequent two months. A subvariety, comprising the fluid group, accounts for many of the late manifestations of cerebral injury, including the debilitating post-traumatic neuroses.

The importance of both types lies in early recognition and surgical treatment. Theoretically, no acute subdural hematoma should ever reach the chronic stage. The diagnosis, possibly suspected from the clinical course of the patient, must usually

be confirmed by exploratory trephination, trans-temporal by preference and bilateral if necessary. Such an operation, in Munro's experience, is never contraindicated in "a patient who has been knocked unconscious by a blow on the head and who is not getting better or is getting worse under adequate lumbar-puncture and fluid therapy." If, as Munro rightfully concludes, these patients are not progressing favorably, "the responsibility rests with the physician to recognize the possibility that a mistake has been made in the diagnosis and that, as a result, he must investigate and treat the cause of this failure to recover by every means at his command." The "means" is the exploratory trephine, lightly, but not derisively, called "woodpecker surgery." In the hands of those specially skilled to carry it out, such surgical treatment not only prevents serious brain damage but also, in many cases, saves lives.

FIFTIETH ANNIVERSARY OF THE GRENFELL MISSION

ON August 4, 1892, a recent graduate of the London hospitals, Wilfred T. Grenfell, landed on the Labrador coast. On that bleak and isolated land, he found British fishermen and trappers who, amid great difficulties, earned a meager living for their families; there he also found poverty and disease unchecked and no physician on over hundreds of miles of coast. Fifty years ago, Grenfell saw and met the challenge, and for the rest of his life, he labored to improve the health and the lot of the fisherfolk of Labrador and northern Newfoundland. Last summer, the ashes of Sir Wilfred Grenfell were buried on the hill above the main mission hospital.

During the years of his active life, the Grenfell Mission, as it is known today, gradually took form, until its work covered over a thousand miles of coast. It grew to comprise five hospitals, as many nursing stations, three schools, a children's home, hospital ships, a marine railway and numerous industrial and agricultural facilities. In spite of his death, and under added difficulties engendered by the war, the work of the mission is

being carried on with these tools, under the supervision of a New Englander, Dr. Charles S. Curtis.

By the constant labors of the staff and through the education of the people, the years have witnessed many medical advances. Beriberi and other deficiency diseases, once all too common, have now nearly disappeared. Epidemics of typhoid fever and diphtheria, with their high mortalities, have been abolished by means of mass immunization. Tuberculosis, a very prevalent disease, is being brought under control. But perhaps most important of all, the people of Labrador now recognize the value of the aid extended to them and are willing to go to the nursing stations or hospitals during the early stages of their illnesses.

Today, as in the past,—when over sixty-five physicians from New England alone have given months or years of service,—much of the mission work depends on the continued support and enthusiasm of volunteer and paid workers. To these, Sir Wilfred Grenfell has left a legacy of spirit and courage for service.

MEDICAL EPONYM

POTT'S DISEASE

Caries of the spinal column and its effect were described by Percivall Pott (1713-1788), F.R.S., surgeon to St. Bartholomew's Hospital, in his "Remarks on that kind of Palsy of the Lower Limbs, which is frequently found to Accompany a Curvature of the Spine, and is supposed to be Caused by It: Together with its method of cure." This appears in Volume 3 (pages 349-385) of the edition of his works published in London in 1779.

The disease of which I mean to speak, is generally called a palsy, as it consists in a total or partial abolition of the power of using, and sometimes of even moving the lower limbs, in consequence, as is generally supposed, of a curvature of some part of the spine. . . . I have, in compliance with custom, called the disease a palsy; but it should be observed, that notwithstanding the lower limbs be rendered almost, or totally useless, yet there are some essential circumstances in which this affection differs from a common nervous palsy: the legs and thighs are, I have just said, rendered unfit for all the purposes of locomotion, and do also lose much of their natural sensibility, but notwithstanding this, they have neither the flabby feel, which a truly paralytic limb has, nor have they that seeming looseness at the joints, nor that total incapacity of resistance, which allows the latter to be twisted in almost all directions; on the contrary, the joints have frequently a considerable degree of stiff-

ness, particularly the ankles, by which stiffness the feet of children are generally pointed downward, and they are prevented from getting them flat upon the ground. . . I found, in infants, in young children, and in those who had been afflicted with the disorder but a small space of time, that the ligaments connecting the vertebrae, which formed the curve, were in some degree altered from a natural state.

When we attribute the whole of this mischief to the mere accidental curvature of the spine, in consequence of violence, we mistake an effect for a cause, and that previous both to the paralytic state of the legs, and to the alteration of the figure of the back bone there is a predisposing cause of both, consisting in a distempered state of the ligaments and bones, where the curve soon after makes its appearance.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

CASE HISTORY SEPARATION OF THE PLACENTA,
COMPLICATED BY CHRONIC NEPHRITIS AND
HYPERTENSION, WITH DEATH OF THE
PATIENT, UNDELIVERED

A thirty-six-year-old multipara, approximately six and a half months pregnant, entered the hospital with acute abdominal pain. Her previous obstetric history revealed eight full term, normal children, the seventh pregnancy four years earlier having been complicated by toxemia and convulsions; this was followed by a normal pregnancy. There was no history of surgical operations or of scarlet fever, but she was known to have had chronic nephritis and hypertension for some years, and examination of the heart had, for some time, shown the hypertrophy consistent with this combination of diseases.

When she entered the hospital, the blood pressure was 230 systolic, 170 diastolic, there was a definite trace of albumin in the urine, and the sediment contained "casts." Examination of the eyes showed papilledema and signs of recent hemorrhage in the retina. The patient was kept under observation for forty-eight hours, at the end of that time, the acute abdominal pain recurred. Examination of the uterus showed it to be tender and firm. There was no mention of bleeding, but a diagnosis of separated placenta was made. Vaginal examination showed a multiparous cervix admitting two fingers. The patient was treated conservatively by the Dublin method: the cervix and vagina were tightly packed with gauze and a Spanish windlass was applied. Since the patient bled through this pack, a Voorhees bag was introduced into the cervix, the vagina repacked, and a transfusion given. She died undelivered, however, shortly after this.

Comment. From the medical standpoint, of course, this patient should never have been allowed

to become pregnant, and in the event of pregnancy, therapeutic abortion was certainly indicated. Any woman with chronic hypertension and nephritis jeopardizes her life when she undertakes pregnancy. This patient received no prenatal care whatsoever, and it is hardly fair to blame the medical profession for the catastrophe. Had she sought medical help earlier in pregnancy, therapeutic abortion should have been advised.

Separation of the placenta as early as the seventh month of pregnancy with complicating nephritis and hypertension is not common but, as evidenced here, quite possible. The blood pressure on entry, the albumin, sediment and casts in the urine, and the eye changes were evidence of very definite kidney damage. The patient was treated ideally—no criticism of her care is warranted. That she should, at this stage of pregnancy, bleed to the point of exsanguination when the cervix and vagina were packed is extremely unusual.

The treatment of this case should have begun with prophylaxis—by the avoidance of pregnancy or by therapeutic abortion and sterilization if pregnancy occurred.

MASSACHUSETTS MEDICAL SERVICE

INCOME LIMITS DETERMINED FOR SUBSCRIBERS

In an effort to create for the low income employee groups a larger measure of protection than a cash indemnity contract provides, the Massachusetts Medical Service faces the unwelcome necessity of determining income limits below which medical service contracts will be sold.

Medical service contracts refer, of course, to the services that will be provided by participating physicians for surgery, obstetrics and diagnostic x-ray studies. The term is used in contrast to the cash indemnity, or limited, contract that will be available to individuals in any income bracket above the specified limits. The Massachusetts doctors are initiating their program by offering this medical service contract only to members of employee groups whose individual income is \$2000 or less or whose family income is \$2500 or less. That such an arbitrary income limit is fair to both the physicians and the subscribers has been determined after serious study of medical service programs throughout the country.

The states of California, Oregon, Washington, Michigan, North Carolina and Pennsylvania, the counties surrounding Buffalo and Utica, New York, and the City of Dallas, Texas, have plans well under way. Within recent months, New Jersey and Colorado physicians have established statewide plans. In all these states, the highest level to which the medical service contract is available ranges from \$2000 to \$3000.

Decisions in these pioneer states were based on surveys of income levels, on the requirements of state insurance departments and on the need for a sufficiently broad base to render enough individuals eligible to meet the percentage requirements for group enrollment.

In California, physicians set the upper level of eligibility at \$3000, the base figure in a comprehensive health-insurance bill that was nearly passed. New Jersey established \$1600 as the level for the family, found it too low and raised it to \$2500 on the basis of government legislation proposed for the low-income group. Michigan established the limit at \$2000 for the individual and \$2500 for the family. Because the state insurance department would not accept lower levels, Buffalo set the limits at \$1800 for the individual, \$2500 for man and wife, and \$3000 for the family. Utica has no limit on eligibility.

BASIC FIGURES RESULT OF STUDY

In addition to the study of the plans operating in other states, the Massachusetts Medical Society has arrived at its \$2500 base figure through a study of income groups in Massachusetts. The most normal of recent years was the year 1939-1940, inasmuch as it was free from the abnormal influences of depression or boom. The study revealed that an individual income level of \$2000 accounted for 83.4 per cent of the wage earners and that a \$2500 family income embraced 91.4 per cent. In the present period of increasing wages, these percentages may be modified. With the increased cost of living, however, individuals within these fixed limits are even more in need of a medical-service program.

Employees whose individual or family incomes place them above the medical-service contract may be enrolled with their group on a cash-indemnity basis. They will receive cash payments for medical services in the amounts specified in their contracts. Since this cash-indemnity subscriber may then be charged by the physician the difference between the latter's fee and the amount guaranteed by the contract, there is virtually no alteration in the present financial arrangement between the private patient and his physician, except that the doctor is assured more prompt payment and the subscriber is enabled to pay his bill more easily.

Summarizing, then, the physicians of the state through the Massachusetts Medical Service are offering medical-service contracts, which comprise surgery, obstetrics and diagnostic x-ray services, to groups of employees whose individual incomes are \$2000 or less and whose family incomes are \$2500 or less, and cash-indemnity contracts for employees whose incomes are above these figures.

WAR ACTIVITIES

PROCUREMENT AND ASSIGNMENT SERVICE

DUTIES OF THE VARIOUS UNITS

The following memorandum concerning the duties of the various units of the Procurement and Assignment Service was recently issued by the executive officer, Major Sam F. Seeley, by order of the Directing Board:

Directing Board

1. Establishment of policies and procedures for the Procurement and Assignment Service.
2. Maintenance of liaison with the appropriate governmental officials and agencies and with the various professional groups.

Central Office

1. Maintain contacts with federal agencies relative to their needs for physicians, dentists and veterinarians, and consultations with these agencies regarding the possibilities of revision of their requests in consideration of the limited supply of professional men in these fields.
2. Prepare quotas of the minimum medical, dental and veterinarian services which should be retained for the civilian population, including private practice, hospital service, industrial service, public-health service and medical education.
3. Prepare quotas for allocating to the states the requests for physicians, dentists and veterinarians needed for war service (these quotas to be determined on the basis of the physician-population ratio in the state, the number of physicians already in service from that state and so forth).
4. Maintain rosters of physicians, dentists and veterinarians:
 - a. Total in the United States.
 - b. Those who have registered with the Procurement and Assignment Service.
 - c. These rosters to contain physician's age, qualifications, location and so forth.
 - d. From these rosters, which will be maintained by the National Roster, names of physicians, dentists and veterinarians with certain qualifications will be obtained from time to time.
5. Secure information for the various governmental agencies in regard to physicians, dentists and veterinarians, as to:
 - a. Availability for service other than in their present location.
 - b. Their professional and other qualifications.
 - c. Their willingness to serve in various capacities during the war emergency.
6. On the basis of this information, select the names of those physicians who meet the specifications of the requisitioning agency.
7. Co-operate with the various governmental agencies in obtaining the applications of those physicians thus selected for service.

Chicago Office

1. Maintain and keep up to date the confidential information concerning all physicians, dentists and veterinarians, with respect to character, type of practice, infringements of law and so forth, which must be considered by the Army, Navy and so forth in deciding whether individuals are qualified for commission.

2 Maintain confidential lists of the relative standing of all specialists (These lists have been developed through the facilities of the American Medical Association, the American Specialty Boards, the National Research Council and confidential advisers representative of the various specialties. This material is to be used by the requisitioning agencies as a basis for assignment of those now on duty and those who are candidates for commission)

3 Furnish assistance of a consultative and advisory nature to the Directing Board and to the various committees of the Procurement and Assignment Service (This includes the utilization of statistical data collected over a period of many years by the medical dental and veterinary medical associations)

Corps Area Committees

1 Supervise the work of the state committees in order that they will be reasonably uniform in the manner in which they carry out the policies of the Directing Board (This will require meetings of the corps area committees with state chairmen and visits by the corps area chairman to the states within his corps area)

2 Act as an appeal board in cases in which the individual physician, dentist or veterinarian, his community or his employing agency differs with the classification given by the state committee

State Committees

1 Obtain the overall enrollment of the professions in the state (This will require the maintenance of rosters in the state offices of those who have enrolled with the Procurement and Assignment Service and those who have not. The former lists will be obtained from the Central Office)

2 Survey local needs for professional services in conformity with the policies laid down by the Directing Board, and on the basis of these surveys determine how many physicians, dentists or veterinarians are needed in the various communities of the states to care for the civilian needs and how many can be released for service elsewhere

3 Determine which particular individual physicians, dentists or veterinarians can be considered available for service elsewhere (In view of the changing circumstances this will require constant reappraisal and obviously can be done only locally)

4 Pass on the availability, character and professional qualifications of individual physicians who are being considered for appointment for service elsewhere for example, for commissions in the Army, Navy and so forth, and

5 Co-operate with the state offices of the Selective Service System in determining whether physicians, dentists and veterinarians who are subject to classification by the Selective Service System are essential in their local communities

6 Maintain lists to be transmitted from the Central Office of those who have expressed their preference for service in industrial practice, civil practice in other communities, state and local health departments and institutions, and act as liaison between these individuals and the industrial organizations, civil practitioners and health departments and institutions desiring the services of these individuals in a temporary capacity for the duration of the war

7 Keep the Directing Board informed of conditions in the state, and bring to its attention matters which may involve general policies

8 Make periodical (weekly) reports to the Central Office of the names and addresses of those commissioned from the state, with information as to which of these have been serving as interns or residents

District or County Committees

1 Provide information, assistance and advice to the state committees in carrying out their functions (Local committees have no authority to make final decisions whether positions or individuals are essential or nonessential)

MISCELLANY

TUBERCULOSIS IN INDUSTRY

As mills and factories hum and as thousands of men and women swell the ranks of labor under the pressure of war industry, problems concerning the health of workers are in danger of being pushed aside. Tuberculosis is one of the notorious wasters of manpower. Special attention must be given to this disease, which affects and is affected by occupation. To help clarify concepts, a symposium on tuberculosis in industry (A symposium on tuberculosis in industry held at the Stranac Laboratory, Stranac Lake, N. Y., in June, 1941, a resume. *J A M A* 118 642-644, 1942. *Tuberculosis in Industry* 374 pp. New York: National Tuberculosis Association, 1942) was held at the Stranac Laboratory, where leaders in health and industry discussed problems that will also interest the general practitioner. A resume of the symposium follows.

The prevalence of tuberculosis in any community is determined by the general standard of living and by the number of open carriers. In particular occupations, the factors of selective employment and unfavorable environment modify the picture. If such factors work involving silica for example are dominant, the incidence in the wage earners will be different from that of their families.

The source of the great bulk of infections is a human carrier with a pulmonary cavity. Although the home is probably the place of most childhood and some adult contacts, many primary infections and more reinfections must occur in the place of work. Nurses, physicians and attendants on the sick encounter a real occupational hazard from infection itself. This hazard should be accepted as incidental to the professional life and hospital management should assume the obligation of minimizing opportunities for mass infection.

About 65 per cent more young women than men die of tuberculosis between the ages of fifteen and twenty five. From a practical standpoint the employer of large numbers of women needs an effective medical department if he would avoid a tuberculosis problem. Race is a factor to be considered but it is so intricately associated with the effects of living standards and environment that its effects cannot be weighed. Nutrition is another important factor but also one of the most difficult to evaluate. The influence of fatigue has been studied in the automobile industry and in a steel mill, in neither of which there was evidence that this factor was responsible for any excess of tuberculosis. The belief that abnormal degrees of temperature and humidity lower resistance has little support. Trauma does not initiate a primary infection of the lungs.

Tuberculosis has been regarded as the great enemy of the printer (printers and printers have about 16 per cent more tuberculosis than all other occupied men), and in turn was attributed to lead poisoning which printers might have contracted. Certain studies indicate that neither lead absorption nor lead intoxication is the cause

Fumes and gases are inhalable, and many of them are sufficiently irritating to provoke severe inflammatory reactions. Mature judgment on the effects of gas used by the armies during the last war reversed the early opinion that this agent was responsible for the many cases of tuberculosis that developed. Routine annual examination of a large group of employees engaged in the manufacture of chlorine, phosgene, hydrofluoric acid and other irritating gases supports the view that exposure to irritant gases is not responsible for excessive tuberculosis.

The general thesis that inflammation of the lungs is necessarily unfavorable to the course of associated tuberculosis has little support. It is probably true that certain kinds of inflammatory reactions may have some influence. The increased incidence of tuberculosis that followed epidemic influenza may have been due in part to pneumonic complications.

In grain handlers exposed to high concentrations of organic dust in unloading lake steamers, 2.5 per cent of a group of 234 showed x-ray evidence of clinically significant tuberculosis, and another 2.3 per cent had old healed lesions. Socioeconomic factors, rather than grain dust, were thought to be responsible. Tobacco dust has been under suspicion as a cause of tuberculosis since Ramazzini's studies in 1700. Yet, in a modern cigar factory with a well-organized medical service and air-conditioned rooms, there was less tuberculosis than in the city where the plant was located. Metropolitan mortality figures for 1937-39 show an index for tuberculosis of 107 in cigar and tobacco factory operatives, but it should be noted that 75 per cent of the labor, which now produces only 25 per cent of the product, still works in small shops without health supervision.

Low rates for tuberculosis were found in the Saranac Laboratory studies of the cement and gypsum industries. The usual number of healed lesions was disclosed, so that opportunities for infections had not been lacking.

All these observations support the view that exposure to organic and nonsiliceous dusts has little influence on susceptibility to tuberculosis. Reports on foundries, quartz mining and the granite industry brought out that higher tuberculosis rates prevail in these trades, that there is a greater tendency for such infection to develop after the age of forty rather than earlier, and that the infection is extremely chronic, often giving no symptoms of intoxication or a positive sputum until shortly before death. In miners, the incidence becomes higher and the prognosis of associated tuberculosis worse as the silicotic reaction increases. Miners exposed to silica dust with no roentgenographic evidence of reaction showed little more tuberculosis than the other members of the community in which they lived. Foundries seem to be responsible for the least amount of tuberculosis, whereas the granite industry probably causes the most.

Vermont marble workers had two and a half times as much tuberculosis as the general population of the state (largely rural) exclusive of the granite center in Barre. By contrast, the rate for granite workers was one hundred and thirty times the general one.

The value of a good industrial hygiene program was brought out by the experience of the Eastman Kodak plant. This program costs \$10,500 annually, but it also costs \$3218 to treat one minimal case of tuberculosis. The attack rate in this plant has fallen from 2.3 at the outset of a study to 0.2 at the present time.

The complexities of compensation insurance carriers were discussed. One plan proposed was that evidence of tuberculosis in any form should preclude employment

in industries with silica or other proved hazards and that compensation should be allowed for all tuberculosis subsequently developing in such employment. In other industries, with no specific hazards, persons with healed tuberculosis should be permitted to work, but no compensation should be allowed for infections that might become active or develop during employment. In view of the evidence that old tuberculosis so rarely breaks down in any industry except industries with silica hazards, this appears most equitable.

In the summary, it was pointed out that, aside from nutrition and socioeconomic factors, silica is the only one that has a recognized effect on susceptibility to tuberculosis. Many industrial conditions popularly accepted as predisposing to this disease are without measurable effect. — Reprinted from *Tuberculosis Abstracts*, July, 1942.

NOTE

At a recent meeting of the College of Physicians of Philadelphia, the Alvarenga Prize was awarded to Dr. Edwin J. Cohn, professor of physiological chemistry at the Harvard Medical School, in recognition of his distinguished contributions to the knowledge of blood proteins.

CORRESPONDENCE

COARCTATION OF AORTA

To the Editor: In the December 27, 1934, issue of the *Journal*, I reported two cases of coarctation of the aorta, in father and son. In the former, the clinical diagnosis has been verified.

A. D. did heavy manual labor from the beginning of 1933 until he died on August 16, 1941. He took 1½ gr. of digitalis daily most of the time from 1934 until his death. Extrasystoles were present at each examination. These persisted when he omitted the digitalis. On April 17, 1936, his blood pressure was 192/102; on August 3, 1940, it was 210/106; and on May 10, 1941, it was 176/96. On the last date, he suffered from loss of memory, and moist rales were heard at the bases of the lungs; no paralyses and no abnormal reflexes were found. He was advised to rest and to continue taking digitalis. However, on May 18, he was found shingling a roof. At that time, the blood pressure was 182/94, and the lung bases were clear. In the late afternoon of August 16, the patient's car, which he was driving, collided with another automobile. He turned to his wife and asked how she felt. On being reassured that she was all right, he stepped from the car to the pavement and at once fell down. A physician who arrived shortly thereafter pronounced him dead.

At the request of an insurance company, the patient's body was exhumed, and an autopsy was performed by Dr. Benjamin Castleman on October 9. Just below the attachment of the closed ductus arteriosus, the lumen of the aorta was completely blocked. There were hypertrophy of the left ventricle and marked sclerosis of the coronary arteries. The aortic cusps were normal. The internal mammary arteries were four times the usual size. The abdominal aorta and the iliac arteries were small.

Immediately after the accident, and at the post-mortem examination, there was no evidence of severe traumatic injury.

NUMBER 4

CESAREAN SECTION IN MASSACHUSETTS IN 1940*

ROBERT L. DENORMANDIE, M.D.

BOSTON

THIS report is the fourth of the five-year study of cesarean sections sponsored by the Massachusetts Department of Public Health and the Section of Obstetrics and Gynecology of the Massachusetts Medical Society.

Questionnaires were sent to one hundred and seventy-two licensed maternity hospitals, and replies were received from all except one small proprietary hospital. The care given the preparation of the replies varied greatly. The co-operation of those hospitals that replied carefully and intelligently to the questionnaires is appreciated. In thirty-nine hospitals, no cesarean sections were performed.

* * *

In Massachusetts in 1940, there were 66,496 live births and 1765 stillbirths, a total of 68,261. Of these, 56,935 were reported to us as having occurred in hospitals. Two thousand three hundred and twelve cesarean sections are recorded. One emergency section was done in a home. There were 21 hysterectomies, making a total of 2333 abdominal deliveries.

The incidence in 1937 was 1:30.3, in 1938, 1:28.7, in 1939, 1:32.2, and in 1940, 1:29.2.

Table 1 gives a summary of the abdominal deliveries. There was a greater proportion of elective sections than before, and a little larger percentage of low sections.

There were 26 of the extraperitoneal type, 16 being of the Waters type. All but 2 of the patients in this group lived. Twenty-two babies lived, but 5 were stillborn. The deaths are discussed below. It should be remarked that the convalescences in this group were greatly improved over those occurring in 1939. In 1 case of the peritoneal-exclusion type, the patient had a stormy convalescence because of sepsis, but eventually recovered. Two others developed sepsis, with stormy convalescence,

and made slow but final recovery. One patient was infected with gas bacillus but eventually recovered.

There were 34 Porro operations, or hysterectomy following immediately or shortly after the cesarean section. The indications for these 34 cases are

varied. Eight were done for uncontrollable hemorrhage. One of these patients, a case of placenta previa, when operated on, was found to have a placenta accreta. Seven operations were done for fibroids of the uterus. In 5 cases, the only reason given was that the patient had had a previous section, but in only 1 of these had two sections been done. In 5 cases, a ruptured uterus was found. The following indications each accounted for 1 case: eclampsia, toxemia, pyelonephritis, age of patient (forty-four), a long labor and patient infected, and a shoulder presentation with a contraction ring. In 1 case, I have classified the indication as bizarre,—"necessity for pelvic operation." In 1 case, there was no recorded indication, and in the final case, the indication given in the questionnaire was "attempted breech extraction, with inability to deliver the head." That indication suggested very bad obstetric judgment, and on fur-

*Presented in part, before the Boston Obstetrical Society, January 20, 1942.

ther inquiry it was learned that the patient was in labor a long time and that x-ray examination showed a breech presentation with a definite hydrocephalic head. Since the fetal heart was heard, the operator did a section and then a Porro. In this group, 14 babies died, and 21 survived. Five of the mothers died, but these are reported under the maternal deaths.

Table 2 records the indications for the hysterotomies, and needs no comment.

Table 3 shows the various types of anesthesia used. The only change noted is the great increase in the use of spinal anesthesia. It should be mentioned that in 1 case the patient was prepared for

occurring in Massachusetts in 1940. In the group classified as "other," there were various combinations of basic drugs with either cyclopropane, ether or nitrous oxide.

Table 4 presents the indications for operation in cases in which the baby was lost. As one might expect, emergency operations accounted for the large majority of these infant deaths. In the elective-section column, several can at once be excluded from criticism. In 2, the babies were macerated. Two mothers had diabetes. One had chronic nephritis, and the section was done in the interests of the mother. Three babies had malformations incompatible with life—meningocele, diaphragmatic hernia and congenital abnormality of the bile ducts. Five deaths in the elective column were assigned to monstrosities; all the fetuses

were hydrocephalic. Not all these cases had x-ray study before operation. Subtracting these 13 cases, there were still 52 elective sections in which the baby was lost. It is unnecessary to review these deaths. It is sufficient to call attention to the fact that serious criticism is justified when a baby is lost following an elective section. Either the time chosen or the technic is at fault, and the operators should rightly be reprimanded.

In the emergency column, as has been remarked in previous reports, it is doubtful if sections should

have been done for the first two indications—separated placenta and placenta previa.

To go over each indication would make a tiresome review, but certain points should be noted. Under "monstrosity," there were 6 cases of hydrocephalus. The majority were not so diagnosed before operation. Malposition of the heart, congenital atresia of the esophagus, and diaphragmatic or ventral hernia cannot be diagnosed before operation, but major skeletal deformities should be, if careful x-ray films are taken.

The chief reason for the loss of the babies under the indication, "previous section," was prematurity. Either labor had begun or the membranes had ruptured before term. Many of these patients were operated on after they were in labor.

It is obvious that the number of babies lost is too large. The operators should weigh the probability of obtaining a living baby more carefully than they obviously did. It is surely questionable obstetrics to do an emergency section because a fetus shows distress, and then obtain a hydro-

cephalic baby. This is true of other indications. Until the infant mortality is reduced, the results in cesarean section cannot be regarded as satisfactory.

Table 5 shows the indications given for operation. It is to be expected that the operations for "previous section" will increase steadily because of the great number of new sections done each year.

I shall not discuss each indication, but there are certain comments that I wish to make. Many of

cause of a multiparous breech is not good obstetrics. Whether many of the transverse presentations could have had external versions or simple internal podalic versions at an elected time is a difficult question to settle, but there has been a great increase in the number of sections for this indication.

Under "dystocia," an attempt has obviously been made to use the test of labor in a greater number of cases. But the test of labor is a very indefinite

the sections for placenta previa were done at five, six or seven months' gestation, with no probability that the babies would live. The same thing is true of the indication, "separated placenta."

The number of cases done because of eclampsia in 1940 was larger than that in any previous year—15. Of course, when eclampsia occurs, somebody has erred, either the patient or the physician. But to subject a woman already desperately sick from eclampsia to a section is regarded by the majority of obstetricians as a doubtful procedure. In 1940, 3 eclamptic mothers died.

Under the indication, "malposition of the baby," an increasing number of sections are done for breech. A section on a primiparous breech may be justifiable in many cases. But to operate be

thing, varying from one or two hours to twenty-four or forty-eight hours, with or without rupture of the membranes. In many of the cases of "labor without progress," it was definitely stated that the patient had had only an occasional pain. In some cases of "cervical dystocia," the patient was not even in labor, and yet a section was done for that indication.

It is doubtful if everyone would agree on the indications classified under "previous surgical operations." Undoubtedly, many of these were justifiable, and to state dogmatically that they were not would be unfair. I have continually questioned the advisability of doing sections on so many patients who have had a repair of the perineum.

ating the indications, "pelvic and uterine surgery." Surely "fracture of both bones, lower leg" is specious. I cannot understand the indications, "perineal abscess" and "acute appendicitis." If the latter was a definite acute appendix, surely to follow it by a section was a very dangerous procedure. In this case, to quote the operator, "it was explained to the husband that a cesarean section was advisable since there would be a great danger of evisceration of the abdominal wound during normal labor, which was due in ten days."

The indications listed under "associated medical conditions" need little comment. It must be remembered that a section in a severe cardiac condition is a serious procedure and not always the best way to deal with the condition. Each year, deaths are recorded in this group, and in 1940 there were 3.

In previous reports, the reason for the increasing number of sections on diabetic patients has been mentioned. In 1940, there were 13 new sections for this condition, and 5 others were classified under "repeat sections." No mothers were lost, but 3 babies died, 1 was macerated, and 1 had a cystic kidney.

A somewhat astonishing indication is "acute back."

Following "associated medical conditions" in this table, one finds a miscellaneous list of indications. Some of these are valid, but others are not.

"Previous obstetric disaster" is in many cases a reasonable indication. But the circumstances surrounding the previous delivery must be thoroughly studied—the type of labor, the size of the baby and, above all, the ability of the physician in charge of that disaster.

In many elderly primigravidas, a section is surely justified, but the mere fact that the patient is older than many women having their first babies is no good indication. The size of the baby, its relation to the pelvis and the condition of the cervix are determining factors. If the decision is to operate, an elective section should give the best results. This year, 2 mothers in this group were lost following emergency sections.

There seems to be no justification for doing a section simply because the patient is young (fourteen), unless there is some definite indication.

The advisability of operating because of fetal distress has been consistently questioned. More justifiable, if conditions are good, is operation for a prolapsed cord when the cervix is not fully dilated.

Regarding the indication, "following operative attempts," it should be repeated that at best this is a dangerous procedure. Of the 8 cases so classified, 4 followed the unsuccessful application of

forceps. Three of these patients had stormy convalescences. One, on whom a Waters section was done, made a good recovery. One baby was lost. Three patients had malformed babies, 1 being a double-headed monstrosity. In this case, the questionnaire states: "Forceps tried and failed, then decapitation and attempted forceps on the other head, followed by attempted version and extraction. Finally a cesarean section of the peritoneal exclusion type was done. After a very stormy convalescence, the patient recovered." It is obvious from the questionnaire that this was a most difficult case to manage, and the operator was fortunate that the patient did not die.

Two fetuses were hydrocephalic. It is stated in one case that a craniotomy was done, but since the head did not engage, a low section was performed. The obstetric judgment in not completing the delivery following craniotomy is open to question. In the other case, the note states, "Attempted breech extraction to midhigh; delivery failed, and a section was then done." This case is considered under the maternal deaths.

The next indication, "for sterilization or by request," cannot be considered justifiable.

Four cases are recorded under "ruptured uterus," 2 being spontaneous and 2 following previous sections. These cases were so diagnosed. There were, however, 6 others that were discovered at operation following previous sections.

The indication, "postmaturity," is questionable, especially when the questionnaire says "one week overdue." In 1 case, the patient was stated to be two and one-half weeks overdue, with a large abdomen; a section was done, and twins were delivered. The mother died. The case is commented on below.

With a known malformation of the fetus incompatible with life, cesarean section is not justifiable without other indication.

In 3 cases, the only indication given was "twins." In 1, the pelvis was reported as rachitic. In this case, the babies weighed 6 pounds, 8 ounces, and 6 pounds, 4 ounces. There were 18 other cases of twin pregnancy and 1 case of triplets, but these were all assigned to other indications than "multiple pregnancy."

In 3 cases, the only indication given was "floating head (patient not in labor)." There was no note of the relation of the size of the head to the pelvis, or whether the patient was approximately at full term. That a floating head can be regarded as an adequate indication is doubtful.

The indication, "Varicosities," is also open to criticism, unless the condition is very severe.

The 19 cases classified as "Bizarre" need not be taken up in detail. Several were classified as "dys-

tocia," although the patients were not in labor. In 2 cases, the only indication was "multiparity." One baby weighed 6 pounds, 11 ounces, and the other weighed 7 pounds, 11 ounces. In another case, it was stated that the patient had "soft-tissue dystocia," and yet there was no labor. In another, the only indication was "necessity for pelvic operation." One indication was, "Severe persisting labor for three days; fainting spells, with vomiting; question of concealed hemorrhage." A section was done, and the baby, in good condition, weighed 7 pounds, 9 ounces.

One indication given was:

The following sociological condition: The patient was living with her husband's family, with no opportunity to go on her own. The family were very critical of her repeated pregnancies, this being her third. Because of this and the facts that she had a third-degree tear with a good repair, that she was very desirous of having her tubes tied off, and that the baby was a large one, a cesarean section was done.

Another indication was a "fixed cervix." What that means, I do not know. There was no labor. The baby was born dead. There was 1 case of "locked twins." In the final case, a classical section was done because "the vagina had been explored at six months." The patient had no labor. The baby weighed 6 pounds, 12 ounces.

There were 63 cases in which no indication was recorded. Doubtless, the indications were good and sufficient, but the questionnaires did not show them.

Table 6 presents a summary of the 41 maternal deaths that occurred in 1940. Deaths from emergency sections are always more frequent than

thrombosis of the superior mesenteric artery, 1 from embolus, and 2 from hemorrhage.

In the first of the 2 deaths from hemorrhage, autopsy revealed a most unusual condition. The patient had had five previous sections. At this operation, a low transverse section was done. At the time of operation, it was noted that the previous incisions were covered by large varicosities. The patient was returned to the ward in good condition. Four hours later, she suddenly went into shock. In spite of transfusion and stimulation, she died. At autopsy, the abdominal cavity contained much blood and one clot the size of a grapefruit.

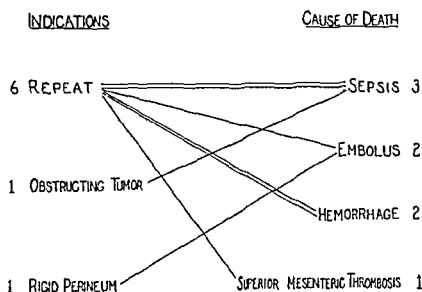

FIGURE 1. Maternal Deaths in 8 Elective Cesarean Sections.

The old scar was gaping wide open, but the new scar was intact. There is no note regarding the varicosities.

In the other death from hemorrhage, the cause given on the death certificate was "shock due to cesarean section." On investigation, it was found that because of excessive loss of blood at the operation the patient was in poor condition. The operator, a general surgeon, left immediately after the operation. In the absence of the operator, treatment consisted in the administration of stimulants.

Two cases were assigned to embolus. I wish to comment on 1. In the questionnaire, the indication for the section was "contracted pelvis, rigid perineum and narrow introitus." Convalescence was normal, and at the end of fourteen days, the patient was about to be taken home when she complained of severe exhaustion and weakness. She suddenly expired from an embolus. It was reported by the investigator who looked up this death that the patient had a transverse position with knee and elbow presenting. On the tenth day, she was up and about to go home when she felt faint and weak and was put back to bed and kept there for two weeks longer. She was about to be transferred by ambulance when she suddenly died. This patient probably did die from an embolus.

those from elective sections. The situation in 1940 is unchanged. The number of deaths following elective sections (8) is the lowest that has been recorded.

The other figures need no comment.

Figure 1 shows the indications and the causes of death in the elective sections. There were 6 repeat sections: 2 patients died from sepsis, 1 from

but the history as given in the questionnaire and the story as obtained by the physician who investigated the death show so great variance both in the indications for operation and in the convalescence that it seems worth noting.

The cause of the final death under elective sections was given as "obstructing tumor." This patient died of sepsis.

Figure 2 shows the indications and the causes of death in the 33 emergency sections.

Ten patients were classified as dying from sepsis. Seven of these were so diagnosed on the death certificate. Of the other 3, one was reported on the questionnaire as dying from bronchopneumonia,

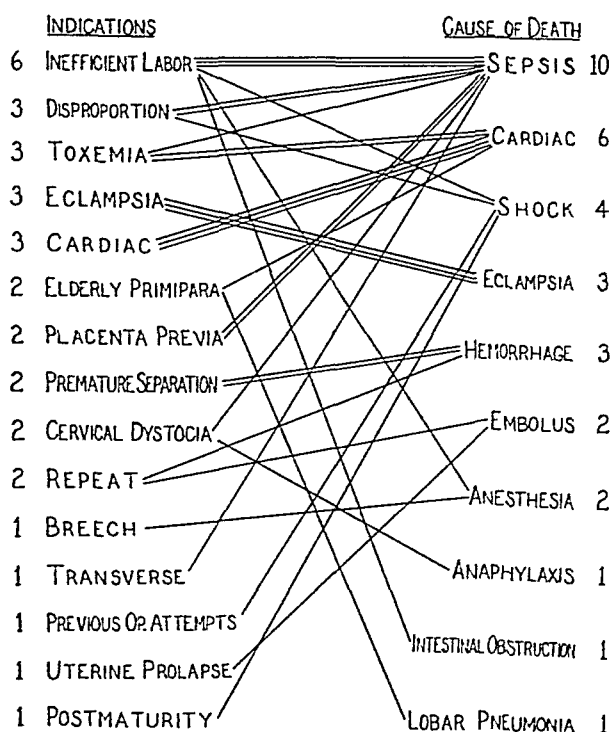

FIGURE 2. Maternal Deaths in 33 Emergency Cesarean Sections.

and another from embolus. The third is considered below. Autopsy on the first of these showed multiple abscesses of the uterine wall and multiple pulmonary emboli. The second patient ran a temperature of 100 to 101°F. each day after the operation. At autopsy, a thrombosis of the pelvic veins was found. This patient undoubtedly had an embolus, but she was also septic and was therefore so classified. Possibly, this death should be classified as due to embolus.

The third case deserves comment. The indication for operation as given in the questionnaire is as follows: "The patient was a para III. Examination showed uterine inertia, primary and secondary; uterine anomaly, nonpathologic; cardio-renal disease; pre-partum toxemia; uremic syn-

drome; and pernicious anemia." The questionnaire states that a classical section was done; the membranes were not ruptured, and the patient was in labor fifty-two hours. The causes of death were given as follows: "pregnancy, uterine inertia, pernicious anemia, post-partum toxemia, intestinal obstruction and circulatory failure."

The investigator's note is as follows:

The patient ran a postoperative temperature of 103 to 105°F. There was no indication of pernicious anemia by signs, symptoms or laboratory study. A low section was done following a twenty-four-hour labor, with full dilatation for four hours. The doctor who operated stated that the membranes were unruptured but bulged out through the vagina. He saw something in the front part of the vagina that he designated "nonpathologic uterine anomaly." The patient had had two normal deliveries.

This patient obviously died of sepsis. The case was misdiagnosed and mistreated throughout. Death must be laid at the door of the physicians and of the hospital that allows such men to carry on.

The indications for the section in 10 patients who died of sepsis were: inefficient labor, 3; disproportion, 2; toxemia, 1; placenta previa, 2; so-called "cervical dystocia," 1; and transverse presentation, 1. In this group, 5 classical sections were done, 4 being of the low and 1 of the Waters type.

It seems poor judgment to do a classical section on a woman who has been in labor many hours with ruptured membranes. The risk that such an operation entails has been established for many years.

Four deaths are classified as due to shock—1 following inefficient labor, 1 with the patient in labor for twelve hours with disproportion, 1 in which an operative attempt failed and 1 with the questionable indication of "postmaturity."

It is interesting to go a little farther into these cases. In the first, the indication was a long labor with a high presenting part and no dilatation of the cervix. The length of labor was not stated. But the physician who investigated the case found that the patient was in labor sixteen hours without progress, that she died four hours after operation and that she was transfused three times.

The second patient died three hours after operation. On the questionnaire, there was no further comment, but it was discovered by the investigator that she had received 21 gr. of Seconal within twelve hours, and it was believed that this large amount of Seconal had something to do with the death.

The case in which operative attempt failed needs explanation. The indication given on the questionnaire was, "On attempted breech extraction to

the midhigh, it was impossible to deliver the child; therefore, a section was done." The patient died of shock an hour after leaving the operating room, and the baby was stillborn. On investigation, the following facts were elicited. The patient had eight living children. The present baby was not of excessive size. The patient had a twenty-four-hour labor, with ruptured membranes. Many vaginal examinations were made. Delivery by forceps was attempted three times, followed by an attempted version and extraction. All this was done previous to a classical section.

In the case in which the indication was given as "postmaturity," it was stated that the patient had a very large uterus and that she was two and one half weeks overdue. The physician tried to induce labor with quinine and castor oil, without effect. The patient was in labor twelve to fourteen hours, when a section was done and twins were delivered, one weighing 5 pounds, 13 ounces, and the other, 5 pounds, 8 ounces. The operation was done by a general surgeon, and there is no record that an x-ray examination was made. There seems no real indication for this section. The patient failed very quickly after leaving the operating room and died soon afterward. The twins left the hospital in good condition.

Six deaths are classified as due to cardiac conditions. Two of these patients were known to have had cardiac conditions during pregnancy. Another was found moribund, supposedly because of a bad heart condition, having had no medical care whatsoever, and the physician did an emergency section in the home without previous preparation, with the hope of obtaining a live baby. The baby was stillborn.

In still another case, the patient was a forty-four-year-old primipara, who apparently had acute cardiac decompensation with pulmonary edema shortly after operation.

Two sections were done because of toxemia, one very severe and the other mild. The latter patient had triplets. She went to pieces shortly after the operation and died in spite of all stimulation. The three babies lived. The other patient was a Christian Scientist who had had no satisfactory medical care. She developed a congestive heart failure while in labor and was digitalized; a section was done under local anesthesia. The baby died.

There is nothing to be said of the 3 eclamptic deaths, except that a section is not at present regarded as good treatment in such cases. The 3 babies survived.

In the 3 cases of hemorrhage, 2 sections were done for separated placenta. In the first of these, the patient had been bleeding off and on during the entire pregnancy. She was hospitalized at the

seventh month and kept in bed for three weeks until it was thought that the baby was viable. At operation, she bled very profusely, and continued to bleed after the section was completed. She was transfused during the section and five times thereafter. An hour after operation, a hysterectomy was done. The baby did not survive. In the other case of separated placenta, the patient oozed from the arm where blood had been taken, and at the operation the uterus failed to contract satisfactorily. Four hours after operation, a hysterectomy was done while she was in very bad shape, and she died half an hour later. She was given a total of 3000 cc. of blood. These 2 cases show the necessity, when the uterus fails to contract, of doing a hysterectomy at once instead of delaying until the patient is in a desperate condition.

The third death was due to placenta previa and placenta accreta. This patient had been in bed at home for three weeks with a small amount of staining of pinkish fluid. She suddenly had a tremendous hemorrhage, and a section was done. As soon as the accreta was diagnosed, a supravaginal hysterectomy followed, but the bleeding continued. The patient died on the table. The baby did not survive.

I have classified 2 deaths as caused by embolus. One followed a repeat section. Following the operation, which was of the extraperitoneal type, the patient ran a fever. She was thought to be in satisfactory condition to go home when she suddenly had an embolus and died. Autopsy showed that there was a small amount of pus at the lower end of the abdominal wound and a thrombosis of the right iliac vein. This patient in all probability had a low grade sepsis.

The other case of embolus needs a little elaboration, for the questionnaire and the report given on investigation of the death are at variance. The questionnaire states that the indication was toxemia of pregnancy due to a nephritic condition, with vaginal bleeding. A classical section was done. An uneventful recovery from anesthesia followed. On the sixth day, the patient had an embolus and died. On investigation, the following facts were discovered. The patient had had two previous normal pregnancies. During this pregnancy, she had had slight irregular spotting. There was no bleeding on entrance or before the operation. The patient was hospitalized at the seventh month, and the hospital record states that there was an existing uterine prolapse. The surgeons in this hospital elected to operate and did a Porro section at seven months. The patient did die from an embolus, but the necessity for the operation is more than questionable.

Two cases are classified as due to "anesthesia"

In one, the indication was a breech, and in the other, inefficient labor. In both cases, the cause of death was given on the questionnaire as pulmonary embolus, but in each case the patient was cyanotic throughout the anesthetic, with a large amount of mucus and frequent vomiting. There is no doubt that both patients had pulmonary edema, and possibly acute dilatation of the heart, but the underlying cause of death was a poorly given anesthetic.

In the next case, in which the section was undertaken because of anaphylaxis, the physician stated in the questionnaire that the death was due to misgrouping. That, of course, may be true, but the question arises whether this death was not connected in some way with the recently discovered Rh factor.

In another case, intestinal obstruction may have been the correct cause of death. The cause as given in the questionnaire was "intestinal stasis, probable ulcer of the stomach." The patient had had three previous abdominal operations. The investigator found that she had given a history of chronic indigestion for several years. She had had vomiting and abdominal pain when seven months pregnant. She vomited a good deal after the operation. At operation, many adhesions were found, and the investigator believed that the death was

in all probability due to intestinal obstruction, which was incomplete at the beginning and later became complete.

The indication for the last case, in which the cause of death was lobar pneumonia, was "elderly primipara." The patient was in labor for some hours. The questionnaire states that she developed lobar pneumonia and cardiac failure and died on the fourth day. No further information is available regarding this case.

It is difficult to say how many of these deaths were preventable, but I think it will be agreed that the number of deaths was greater than it should have been. There were 219 maternal deaths in Massachusetts in 1940, giving a death rate of 2.8. But it must be noted that cesarean section figured in nearly 19 per cent of the deaths. There is no doubt that the results obtained were remarkably good. However, the fact remains that altogether too many sections are being done.

In 1940, there was a greater variance between the statements on the questionnaires and the facts elicited by the investigators. It was obvious in some cases that the questionnaires covered up the actual causes of death and the indications for operation.

THE TREATMENT OF PSORIASIS WITH A SARSAPARILLA COMPOUND*

FRANCIS M. THURMON, M.D.†

BOSTON

SARSAPARILLA has been used as a medication since 1603, when Martin Pring,¹ in the English ship *Speedwell*, searched the New England coast for forests of sassafras, which then was considered "a panacea for all manner of disease." In America, the earliest colonial settlers purveyed sarsaparilla as the inevitable spring tonic, attributing to its use a diuretic, diaphoretic, tonic and alterative effect. By 1892, Schulz² recognized the fact that there were different varieties of this dried root of the *Smilax* species and believed that he had isolated three distinct saponins from sarsaparilla: parillin, sarsasaponin and smilasaponin. Since the observation of Schulz, a voluminous literature on the saponins has accumulated. It is the water-soluble saponin called sarsasaponin (parillin), obtained from the Honduras variety of sar-

saparilla, that forms the active ingredient of the tablets used in this study.

A survey of the literature, covering fifty-two original articles, on the chemical composition of the various types of sarsaparilla, the nature of the saponins and the structure of the sapogenins reveals that only one definite saponin has been isolated from any of the varieties of sarsaparilla. This compound is generally called "sarsasaponin (parillin)." Its chemical constants are: melting point, 238 to 240°C. (Van der Haar³) and formula, $C_{45}H_{74}O_{17}$. On hydrolysis with dilute acid, it yields one molecule of sarsasapogenin (parigenin), two molecules of glucose and one molecule of rhamnose. The Honduras and Mexican varieties apparently contain no other saponins.

In sassafras and various other plants distributed throughout the botanical realm, one finds a group of compounds referred to as the "digitalis saponins (and sapogenins)." These digitalis saponins, of

*From the Department of Dermatology, Tufts College Medical School, and the Clinic of Dermatology and Syphilology, Boston Dispensary.

†Assistant professor of dermatology, Tufts College Medical School; physician-in-chief, Clinic of Dermatology and Syphilology, Boston Dispensary.

which sarsasaponin is one, are not to be confused with the "cardiac glycosides" obtained from digitalis plants. The term "digitalis saponins" is purely a chemical classification, and a confusing one at that. Chemically, the two substances are sharply differentiated. Each has quite different and characteristic side chains. The digitalis saponins have none of the physiologic action on heart muscle that characterizes the cardiac glycosides, which also contain unusual sugar molecules not found elsewhere in nature. A still further differentiation lies in the ability of the digitalis saponins to hemolyze erythrocytes in very low concentrations. The sarsasaponin product used in this study is prepared from a particular sarsaparilla and embodies no possibility of contamination with the digitalis cardiac principle; furthermore, the standardization of this sarsasaponin compound by the hemolytic index serves so completely to control optimal quality and uniformity of composition that hemolysis does not present a problem.

Ransom,⁴ in 1901, in an out-moded way, demonstrated a chemical affinity between the saponins and serum cholesterol by which the saponins acted on tissues without causing hemolysis. This affinity of saponins for cholesterol led Deneke,⁵ in 1936, to utilize the studies that Grutz and Burger⁶ had completed three years earlier. Grutz and Bürger found that patients with psoriasis (as compared with nonpsoriatic persons, showed an increase, respectively, in total blood fat of 44 per cent, cholesterol 33 per cent, and phosphatides 43 per cent. Following this, they naturally restricted the fat intake of patients with psoriasis. Deneke advanced farther, by supplementing the fat-deficient diet with the oral administration of sarsaparilla, hoping to utilize the chemical affinity of the sarsaparilla saponin for cholesterol. This procedure met with some success.

Not all patients with psoriasis, however, have a disturbed lipid metabolism. Hering,⁷ in 1938, duplicating the work of Grutz and Burger, observed that the phosphatide content of the blood approached normal levels, and that the free and esterified cholesterol showed no significant deviations from normal. Hering did not believe a relation existed between psoriasis and a disturbed metabolism of fats. Rosen et al.,⁸ in 1937, concluded that the psoriatic process involves hypcholesteremia rather than hypercholesteremia; moreover, on the basis of cholesterol tolerance tests, the author asserted that it is not possible to assume that a disturbance of lipid metabolism is present in patients with psoriasis. Grubb,⁹ in 1935, assuming psoriasis to be a deficiency disease in which the vitamins of animal fats were lacking, prescribed a diet rich in butter (fat) for 3 patients

in whose diets butter had been previously prohibited, and the psoriasis disappeared in a short time. Madden,¹⁰ in 1939, using cholesterol tolerance tests, observed that hypercholesteremia did not generally exist, but that a low-fat diet was of definite value in 68 per cent of cases tested. Madden's patients were hospitalized. He inclined to the belief that the favorable effect of diet might be explained on the basis of a general realignment of metabolism, rather than because of the correction of a disturbed fat metabolism. He asserted that sarsaparilla, because of its saponin content, has an especial affinity for cholesterol and that its ingestion tends to restrict excesses. Stewart et al.,¹¹ in 1939, observed in 6 cases of psoriasis, that 3 patients had lipemia, 2 had blood lipid values within normal range, and 1 showed subnormal values. Despite these conflicting observations, Wise and Sulzberger¹² state that there is no doubt that certain cases of psoriasis are much improved by a strict "fatless" diet. Their special article on psoriasis and its treatment is an excellent contribution, and should be read by all who are interested in this disease.

To Philippsohn¹³ should go the credit for modernizing the old observation that sarsaparilla possessed value as a medicine. His successful use of sarsaparilla in the treatment of psoriasis is interesting. Patients were instructed to make their own compound. Into 1000 cc. of tepid water, 15 gm of sarsaparilla was placed. This was done in the afternoon, and the mixture was allowed to stand overnight, and then boiled for twenty minutes the following morning. While the mixture was still hot, the patient drank half the liquid that morning, the remainder being consumed during the afternoon of the same day. Usually after a week of this daily procedure, decreased desquamation occurred, which, after its complete disappearance, was marked by a smooth red macule that eventually faded. Philippsohn noted no untoward effect from sarsaparilla. One patient who had used the mixture daily for twenty years failed to experience a single relapse of a previously stubborn psoriasis.

Ritter,¹⁴ using the sarsaparilla tablets of Burger, treated 19 private patients. Ten tablets were administered daily. Nine patients became completely or nearly completely free from psoriasis. The shortest required duration of treatment was two weeks, the average period being sixty to one hundred days. Five cases showed improvement but did not completely clear. Five patients showed no improvement at all. On the 10 patients without satisfactory response, Ritter also used a low-fat diet, bland ointments, salicylated vaseline, precipitates and chrysarobin. No harmful or toxic effects were observed.

Zaun,¹⁵ in 1938, treated 20 cases of psoriasis, using five to thirty sarsaparilla tablets daily, a low-fat diet and a salicylated ointment locally. Satisfactory results were obtained in all cases except a few in which the patients failed to follow treatment as advised.

Wise and Sulzberger¹² describe the use of sarsaparilla tablets as a treatment for psoriasis. Baird¹⁶ comments conservatively on the results obtained in 6 cases treated with sarsaparilla.

With an appreciation of the facts as outlined above, there appeared a certain logic in the thought that the standardized, nontoxic, water-soluble fraction of sarsaparilla (sarsasaponin) should possess virtues in the treatment of psoriasis. The present communication is a report of such a study.

CLINICAL MATERIAL

This clinical study covers the past two years. A two-year period was deemed necessary because of the desirability of studying the effectiveness of sarsasaponin tablets on the seasonal variations of psoriasis and its efficacy in controlling recurrent eruptions.

Ninety-two patients were studied. Of these, 75 were treated with the sarsasaponin tablets, and 17 were used as controls. Twelve additional cases were started, but failed to continue a sufficient period to merit inclusion in the series. There were 53 females and 39 males, a ratio of 1.3:1. The average age of onset was twenty-nine years. The youngest patient was three years of age, and the oldest seventy-six. The earliest age of onset was infancy, and the latest sixty-seven. The average duration of psoriasis was ten years, the shortest being three weeks, and the longest fifty-two years. Thirty-seven patients had psoriasis ten years or longer.

A history of familial incidence was obtained in 15 cases (16 per cent). The parents of 5 patients had psoriasis. In contrast, 53 (20 male and 33 female) were the parents of 121 children, and in no case did psoriasis appear in their progeny. This observation indicates clearly that psoriasis is not a deterrent to marriage and the begetting of progeny. Third-generation psoriasis was not noted. The patients were American, English, Canadian, Scottish, Irish, Swedish, Russian, Lithuanian, Portuguese, Jewish, German and Italian.

Objectively, the lesions were of the type and distribution generally described as psoriasis vulgaris. Arthritis or rheumatic joint disease was present in 13 cases (14 per cent). There were no cases of psoriasis pustulosa. Characteristic polymorphism of the lesions was apparent. Large plaque-type lesions were present in 42 per cent. Expressed in percentage, the following areas were involved: scalp, 74; trunk, 60; elbows, 60; knees, 53; nails, 32; genitals, groins and gluteal crease, 36.

The subjective symptoms of itching and burning at one stage or another were unusually frequent, being present in 68 per cent of the cases. Nervousness, a tendency to worry, and vasomotor instability, which, when acute, accentuated pruritus and frequently stimulated the appearance of new crops of lesions, were noted in 36 per cent. A seventeen-year-old boy, brooding over his psoriasis, made four attempts at suicide. One patient, on the death of her husband, quickly developed a fresh exanthematous spread of new lesions. One patient, a student at a local university, was also a student aviator. Owing to storms and bad weather, there was no flying in February, and his psoriasis began to clear. Then came the time for his first solo test flight. Apparently, the nervousness and excitement in anticipation of this examination proved sufficiently stimulating to cause improvement of the lesions to cease, and his psoriasis became quite active and more widespread.

There were several examples of polysensitivity among these cases, such as asthma, hay fever, urticaria and eczema, which had occurred in antecedent members of the patient's families, although a family history of psoriasis was not necessarily present.

The histories in 85 per cent revealed a distinct tendency for the psoriasis to improve during the warm summer months. All patients were warned about overexposure to the sun, yet, in 5 cases of severe sunburn, fresh outbreaks of punctate, guttate or nummular lesions occurred. In New England, the predominant periods for recurrent eruptions are September and October, and March and April, whereas during the winter, when skins and scalps are dry, nails are brittle, and seasonal keratotic follicularis is marked, the psoriatic patient is hard pressed. The patient with psoriasis apparently has a peculiar inherent physiologic habitat on which any number of factors and circumstances may prove stimulating, and when present in sufficient force the inevitable cutaneous response is one of psoriasis.

In all cases, syphilis was ruled out as an etiologic factor, either by treatment or by physical examination and negative Hinton, Wassermann and Kahn reactions of the blood. In 4 cases in which syphilis was present, it was of the tertiary type, and treatment did not influence the psoriasis, except occasionally to produce an accentuation of the lesions. A careful check was kept on the renal status and the hemoglobin and blood counts all through this study. In no case was there evidence of renal irritation. Blood counts performed before, during and following treatment with the sarsasaponin tablets failed to reveal evidence of hemolysis. Three patients showed a rise in hemoglobin from 10 to

15 per cent. The erythrocyte count either held its level determined prior to treatment, or showed an increase of as much as 750,000 cells. The leukocyte count seemed unaffected. The differential counts were not remarkable except for a fairly consistent though mild eosinophilia. The blood smears invariably revealed a goodly number of platelets in all preparations.

TREATMENT

Dosage

It is essential that the sarsasaponin tablets be taken regularly. It is advisable, at the start, to prepare the patient for a three to seven months' course of the medication. If a shorter period is required, so much the better.

The usual adult dose is one tablet* twice daily, preferably taken with a warm liquid at a time when the stomach is likeliest to be empty. These two periods are the early morning on arising and the last thing at night before retiring. A larger dose, two tablets twice daily, or even two tablets morning and evening and one at noon before luncheon, may unhesitatingly be administered. For children aged five years or under, half a scored tablet given twice daily is sufficient.

A diet low in fat will prove beneficial for a large number of patients. Liquids in the amount of 1500 cc. or more daily are recommended.

It should be stated that, for the purpose of this investigation, the tablets used were less concentrated than those that are commercially available at present. A single tablet of the dosage described above contains the equivalent amount of sarsasaponin contained in five of the tablets used in the clinical evaluation. This concentration of the active ingredient of five of the old tablets into one of the new tablets was considered advisable merely as a convenience for the patient. The new tablet is scored; the smaller and older tablet is not. All statements regarding the sarsasaponin tablets in this paper, therefore, apply to the smaller, older tablet of weaker strength. Its equivalent in new tablets may be obtained by dividing by five.

Local Therapy

During the first twelve months of this study, no diet or topical applications were prescribed. During this period, it was shown that the tablets were nontoxic and therapeutically effective. With these two points cleared, there could be no logical objection to a local therapy designed to hasten involution of the lesions, provided that this therapy was not irritating. Consequently, a variety of topical applications were used. They comprised, chief-

ly: irradiation in the form of sunshine or ultraviolet lamp, boric acid ointment, lanolin, petrolatum, olive oil, mild precipitate ointments, salicylic and sulfur preparations, and modified coal tars. Of these, the most effective agents were irradiant energy and a modified coal-tar preparation, Ultrone Ointment.[†] This ointment is a clean, gray to white, nonirritating preparation, which has as its active ingredient the distillate of coal tar. The 2.5, 10 and 20 per cent concentrations proved exceedingly beneficial as a topical application twice daily. One can state definitely that the oral administration of the sarsasaponin seemed to enhance the effectiveness of treatment locally.

RESULTS

Table 1 shows that in the group treated with the sarsasaponin tablets there was a satisfactory improvement, as compared with the condition of the controls. By combining the results of moderate and marked improvement, the percentage that may be considered good was 62. Eighteen per cent of cases

TABLE 1. Results of Treatment with Sarsasaponin Tablets.

RESULTS	TREATED CASES		CONTROL CASES	
	NUMBER OF PATIENTS	PER CENT-AGE	NUMBER OF PATIENTS	PER CENT-AGE
Clearance (100%)	14	18	1	6
Marked improvement (75%)	16	21	6	36

cleared completely. The data on improvement compares favorably with Ritter's¹⁴ experience in 19 private patients treated with the sarsaparilla tablets of Bürger. Nine of Ritter's patients (48 per cent) became completely or nearly completely free of psoriasis, 5 (26 per cent) showed some improvement, and 5 showed no improvement.

In the 14 cases that cleared, the average period of treatment was four months; the shortest period was four weeks, and the longest seven months. The average period of remissions was eight months, the shortest being three months and the longest twenty months. An analysis of these cases reveals that the greatest clearing occurred during the late spring and summer (Table 2). The experience of two full summers showed no photosensitive effect from the sun. As a matter of fact, there is a distinct impression that the tablets enhance the effectiveness of mild sunshine.

Forty per cent of the patients showed moderate or marked improvement. Most of them also

*The sarsaparilla (Sas Par) tablets used in this study were supplied by First Bischoff Company, Incorporated, Ivoryton, Connecticut.

[†]This mixture is manufactured by Lamy Chemicals, Incorporated, Boston.

showed the greatest benefit during the warm summer months. This cannot be entirely attributed to the direct effect of the sun's rays, because many of the patients had indoor occupations and little or no opportunity for beach or sun bathing. There is something about the warmer seasons of the year that is beneficial to psoriasis.

Recurrent eruptions most commonly appeared in the fall, winter and spring. Although the administration of this sarsaparilla saponin did not completely control these recurrences, their intensity was considerably modified and less severe as compared with similar periods of cold weather during

TABLE 2. *Analysis of 14 Treated Patients Whose Psoriasis Cleared.*

TOTAL PERIOD OF TREATMENT MONTHS	NO OF TABLETS REQUIRED	PERIOD OF TREATMENT	RECURRENCE OF PSORIASIS	LENGTH OF REMISSION MONTHS
1	225	February	January	11
2	525	June-August	May	9

7	2325	October-May	September	4
7	2416	November-June	None	18

preceding years. The dissemination of the eruption was less widespread, its course was milder, the response to local therapy was better, and itching was not nearly the uncomfortable factor that it had usually been. In many cases, the control of pruritus was dramatic. In others, itching was intense, regardless of what was used.

Of the 13 cases of arthritis or rheumatic joint disease and psoriasis, nothing definite can be said about relief of pain. One patient, a sixty-six-year-old man, had painful arthritic involvement of the wrists, hands and right ankle; he received 2925 sarsasaponin tablets over a nine months' period, and it was not until the last three months (October, November and December) of treatment that relief from pain and improvement of the psoriasis were obtained. A forty-three-year-old woman had severe generalized psoriasis including the scalp and nails, and nodular painful arthritic deformities of the hands. She took 5900 sarsasaponin tablets for twenty-one months. The arthritis and psoriasis, including the scalp and nails, were markedly improved. She gained weight, the psoriasis underwent two almost complete remissions, and during the past winter her arthritic pains and psoriasis were so slight as not to be noticeable. She continues to take the sarsaparilla tablets. Another patient, a seventy-six-year-old woman, had painful

arthritis and a chronic, generalized, plaque and papular psoriasis of twenty-two years' duration. The scalp, nails, genitals and gluteal crease were also involved. Her greatest relief was obtained from the sarsasaponin medication. In twenty-two months, this patient took 6075 tablets, and, although the psoriasis was not completely controlled, improvement was moderate, and she continued to take the sarsaparilla compound. In contrast to these favorable impressions, there were similar cases in which the arthritic pains and psoriasis continued apace despite the saponin medication.

Twenty-six cases (35 per cent) of the series showed slight to no improvement, and in 2 (3 per cent) the psoriasis was distinctly accentuated. Thus, in 38 per cent, the response was not favorable. In the light of present knowledge, no adequate explanation for this failure may be advanced. The average period of treatment was three months, and the average number of tablets administered was 942. If this group is contrasted with the successful cases, which required an average of four months to establish a remission, a fair trial period of the tablets is three or four months.

A typical case with complete remission is that of a thirty-two-year-old man. His psoriasis was of eighteen years' duration and generalized—in fact it was so severe that he went outside only at night. There was slight improvement from sun bathing and the use of an ultraviolet lamp, but at no time was there complete clearing. In November, 1939, the patient began sarsasaponin, taking five tablets twice daily. A low-fat diet was advised, and no local therapy was prescribed. Within two weeks, there was a noticeable reduction in the eruption, and pruritus was controlled. The dosage was increased to eight tablets twice daily. Within the next four weeks, the scalp was greatly improved, the scalp hair regained a natural waviness and luster, and the previously extensive eruption on the face was indicated only by erythematous macular patches. Within ten weeks from the start of this medication, only a few patches of psoriasis remained on the arms, chest and thighs. In February, a slight exacerbation of the eruption occurred. At this time, the patient had been without the tablets for a week. On resumption of sarsasaponin, the new lesions quickly vanished, and favorable progress, although slower than at first, was steady. By June, 1940, seven months later, there was no trace of the psoriasis. All areas, including the scalp, groin, elbows and knees, were completely clear.

The effect of a low-fat diet seemed to be helpful. Twenty-four patients were advised to eat as little fatty food as possible during the period of treatment. Of these, 50 per cent showed marked im-

provement, and 16 per cent, complete clearing, whereas the remaining 34 per cent were either slightly improved or less. There can be no doubt that certain cases of psoriasis are improved by the use of a low-fat diet.

The results attained by the use of the saponin of sarsaparilla were superior to those with the usual procedures commonly applied in the 17 patients used as controls. Table 1 amply illustrates this point.

The control cases received dietary management, local treatment, such as Alpine sun lamp, cold quartz ultraviolet radiation, sunshine and ointments of various kinds, including salicylic acid, sulfur, precipitates and coal and wood tars, colloidal manganese, bismuth and liver extract intramuscularly; arsenic in the form of Fowler's solution; and vitamins A, D and B complex orally.

DISCUSSION

The results attained in this series of 75 treated cases of psoriasis were neither remarkably successful nor disappointing. They were far better than average. In certain cases, they were brilliant. Emphatically, sarsaponin is worthy of clinical trial in any case of psoriasis. No toxic systemic effect from its use was observed. A careful check on the cardiovascular, renal, gastrointestinal and hematopoietic systems failed to reveal any untoward reaction. In contrast, many of the patients developed increased appetite, gained from 4 to 12 pounds in weight, and seemed less nervous, slept better and experienced less itching. Three women took the sarsaponin during pregnancy without ill effect, and their psoriasis simultaneously improved.

One distinct impression regarding sarsaponin therapy is that the drug has a greater value in clearing the chronic, large, plaque type of lesion than it has in controlling the recurrent evanescent and exanthematous punctate, nummular and guttate lesions. The individual new recurrent crops of eruption, in most cases, were milder, but they did appear despite the sarsaponin medication.

These cases gave rise to the impression that vasomotor instability, blond complexion and a tendency toward anxiety, worry and nervousness are not causative or even predisposing factors

to the occurrence of psoriasis, but that psoriasis runs a more recalcitrant course in a person possessing this triad.

The tragic and conditioning features of psoriasis on the behavior of this small group is illustrated by one suicide, one attempt at suicide, two adolescents with mental reactions of inferiority that led to strange and perverted behavior, several cases of refusal to marry, and numerous patients with neuroses because of their disfigured appearance.

SUMMARY AND CONCLUSIONS

A new drug, the water soluble saponin, called "sarsaponin (parillin)," obtained from Honduras sarsaparilla is described. The technic of its administration and its effectiveness in 75 patients with psoriasis are discussed. Seventeen additional cases served as controls. The study covered two years.

Observations from the literature concerning the nature of the sarsaparilla saponins and the influence of lipid metabolism on psoriasis are made.

When administered orally, the sarsaparilla tablets had a decided and beneficial effect on 62 per cent of patients with psoriasis.

A MECHANISM FOR SYNCOPAL ATTACKS ASSOCIATED WITH PAROXYSMAL AURICULAR FIBRILLATION

WILFRID J. COMEAU, M.D.*

BANGOR, MAINE

FROM a clinical standpoint, the mechanism of attacks of faintness or of actual syncope may be extremely obscure even after considerable study, since observation of the attack is often necessary to clarify the problem. In patients with rather infrequent attacks, such observation is entirely fortuitous unless they can be produced at will, and consequently the primary mechanism of the seizures usually remains a matter of speculation. Contrary to popular belief, organic heart disease is an uncommon cause of syncope, and such cases are confined largely to ventricular arrest due to interference with the conduction system as a result of coronary-artery disease and to the even rarer syncopal attacks associated with aortic stenosis or the shock of severe coronary insufficiency.

It is known that exaggerated vagal reflexes can cause functional disturbances in the regulatory mechanism of the normal heart, resulting in ventricular or complete cardiac arrest, and can thereby produce cerebral ischemia and syncope by a secondary lowering of the blood pressure. The sensitive carotid sinus, for example, at times acts in this manner to produce fainting. Furthermore, it is known that vagal stimulation may be a factor in precipitating auricular fibrillation.

It has been recognized for many years that faintness and syncope may be associated with attacks of the various paroxysmal arrhythmias. Although usually attributed to a drop in blood pressure consequent to the rapid ventricular rate, I believe the primary mechanism responsible for syncope in these cases has never been adequately demonstrated. The chance observation of the following case during a syncopal attack throws new light on a mechanism producing syncope in some of these cases.

CASE REPORT

G. H. B., a 40-year-old married male nurse, was first seen in February, 1941. Since 1932, his usual good health had been periodically marred by attacks of faintness or syncope followed by short bouts of palpitation and irregular heart action. While feeling well and for no apparent reason, the patient experienced attacks of faintness or loss of consciousness of several minutes' duration, following which he was aware of irregular heart action that ceased abruptly within 30 minutes to several hours. Other than causing some heart consciousness, the palpitation was not particularly uncomfortable and produced no ill effects. To the patient's knowledge, no convulsions had ever been associated with the syncopal seizures. These attacks usually

recurred for a day or so and then disappeared for periods varying from several months to several years. Since the onset, six or seven episodes had occurred, the last in 1938, following which the patient had consulted a cardiologist, who had found no physical abnormalities. Lumbar puncture, the Wassermann reaction, blood-sugar curves, the basal metabolic rate and electrocardiograms had always been normal.

The present episode, typical of those in the past, had started 36 hours previously, during which the patient had had several attacks of faintness and one attack of syncope. While the patient was being examined, he suddenly stated that an attack was coming on, and loss of consciousness gradually supervened, with progressively increasing ashen pallor, eyes at first staring and then rolling upward, and a cold clammy skin. The heart sounds, which had previously been audible and regular, ceased (no auricular sounds were heard), and asystole continued for at least 15 seconds, following which three or four slow irregular beats — at intervals of 2 or 3 seconds — were heard; gradually, an irregular rhythm was established at approximately 80 beats per minute, and consciousness returned. Afterward, the patient had no complaint except for irregular palpitation and a feeling of weakness. This bout of palpitation lasted about 3 hours and then ceased abruptly. When the patient was seen 3 days later, there had been no further attacks, and the attack observed was apparently the last of the present series.

The electrocardiogram taken during the irregular rhythm showed flutter fibrillation, with occasional ventricular ectopic beats at a ventricular rate of about 85 beats per minute (Fig. 1). The electrocardiogram taken 3 days later was entirely normal (Fig. 2).

Complete physical examination and fluoroscopic study of the heart and lungs several days after the attack showed no abnormality. The carotid sinus was not unduly sensitive.

It is of some interest that the sequence of events in this case parallels the findings of Iglaue, Davis and Altschule† and others who have induced auricular fibrillation in normal animals by vagal stimulation. It has been observed that auricular fibrillation, when produced experimentally by vagal stimulation, is not infrequently preceded by a short period of heart block; in a dog in which fibrillation was prolonged, the ventricular rate was slow. The ventricular rate of paroxysmal auricular fibrillation in human subjects is usually quite rapid (125 to 150), and it is therefore worth noting that in the case presented the ventricular rate averaged only 85 beats per minute. Exactly what type of heart block occurred is unproved, since good fortune did not extend itself to the point of allowing an electrocardiographic registration of this period.

FIGURE 1. *Electrocardiogram during Paroxysmal Auricular Fibrillation.*

FIGURE 2. *Electrocardiogram during Normal Rhythm.*

It seems probable, however, that complete cardiac arrest (sinoauricular block) occurred rather than auriculoventricular block with only ventricular arrest. In any event, it seems but a short step from cardiac standstill caused by a vagotonic influence to auricular fibrillation due to the same mechanism.

DISCUSSION

It is also of interest to carry to the auricles the analogy of the events known to occur in the ventricles during Adams-Stokes seizures associated with complete auriculoventricular block, in which syncopal seizures are likeliest to occur during the paroxysmal stage of complete heart block; once the block is permanently established, the fainting attacks usually disappear. It has been shown electrocardiographically that there is frequently a latent period, with complete ventricular arrest and a syncopal attack, between the cessation of normal rhythm and the establishment of an idioventricular rhythm. It is possible that in the case presented above a similar latent period affecting the auricles, with consequent cardiac arrest, occurred between the cessation of activity in the sinoauricular node (sinoauricular block) and the establishment of auricular fibrillation. Since a common interpretation is that the paroxysmal auricular arrhythmias are

due to auricular irritability, it may be that in some cases these arrhythmias represent an auricular escape as a result of a depressed sinoauricular node instead of the commoner ventricular escape. Depression of the sinoauricular node is usually functional and the result of vagal activity, although there is some evidence that in older patients the node may be depressed as a result of impaired circulation due to coronary-artery disease.

Of the two possible mechanisms discussed above, the former appears to rest on a sounder experimental foundation and seems the more probable. Both, however, are purely speculative so far as the present case is concerned.

CONCLUSIONS

Faintness and syncope associated with some cases of paroxysmal auricular fibrillation may not be due to a fall in blood pressure and cerebral ischemia as a result of a rapid ventricular rate but rather to asystole during a latent period between the cessation of normal rhythm and the establishment of the auricular arrhythmia. Either the cardiac standstill or the auricular fibrillation, or both, may be of vagotonic origin.

MEDICAL PROGRESS

PHYSIOLOGY*

HEBBEL E. HOFF, M.D.†

NEW HAVEN, CONNECTICUT

SURGICAL PHYSIOLOGY

NO SMALL part of medical progress arises from the attempt to express the changes taking place in disease in terms of the physical sciences and it is no longer necessary to defend the advantages of a scientific training as a basis for a career in medicine. One of the more interesting indications of the popularity of this trend is the appearance of books that purport to interpret to the practicing physician one of the basic sciences involved in his specialty. One remembers Hewlett's *Pathological Physiology of Internal Disease* as an earlier work of this kind. Peters and Van Slyke's *Quantitative Clinical Chemistry* is without question the model for all subsequent attempts,

and establishes criteria by which they must be judged.

The first essential of a book of this kind is that the material it presents and the statements it makes should, so far as possible, be correct, or should represent the result of a rational criticism of available data. Secondly, the applicability to man and to the specialty of the material presented should be most carefully scrutinized. Thirdly, the author should take pains to point out subjects in need of clarification, and should facilitate more extended study by careful documentation at every point. Finally, there is the requirement of completeness of coverage, not demanded in a monograph, but essential in a book of this type.

Judged by such rigorous standards, a recent volume, *Surgical Physiology*, by Nash¹ falls somewhat short of expectations. There seem to be no gross errors in fact, but a number of minor flaws can be seen, such as the statement (page 34) that

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

*From the Laboratory of Physiology, Yale University School of Medicine.

†Associate professor of physiology, Yale University School of Medicine.

ordinary fainting attacks are "largely due to vagal slowing of the heart." An example of uncritical handling of material is the discussion (page 43) of plasma potassium in shock without reference to the physiologic effects of potassium, or the possible toxic effects of an elevation of plasma potassium. A typical example of failure to consider the applicability to man of physiologic data is the assertion (page 5) that "experimentally an excess of calcium ions causes standstill of the heart in extreme systole, a condition known as 'calcium rigor.'" This phenomenon occurs in the frog and turtle heart, but not in the mammalian heart, in which ventricular fibrillation or arrest without rigor may be the terminal event. The bibliography is limited, and not in a very useful form, and most statements are without documentation. Among the problems dealt with inadequately or not at all are the cardiovascular complications in anesthesia, the lymphatic system and the clotting of blood.

There is perhaps another way of judging this book. It does present material that is rather widely diffused in the literature, and thus serves as a compact and ready source of the salient points of many a subject.

A surgeon with ready access to a well kept library would probably be better satisfied to consult, first, Wigger's *Physiology in Health and Disease*, Best and Taylor's *The Physiological Basis of Medical Practice* or—what in my opinion is still better—Bard's *Physiology in Modern Medicine*, and then to continue the subject in a specialized monograph like Peters's *Body Water* or Salter's *The Endocrine Function of Iodine*. Finally, he could work through the specialized reviews in journals into the original articles. Surgeons not so fortunately situated will find Nash's volume of considerable assistance in reaching an understanding of the physiologic basis of their surgical problems.

ROLE OF VEINS IN SYNCOPE AND SHOCKLIKE STATES

Sudden collapse after what may have been a trifling injury, or following an unexpected fright, is a phenomenon commonly enough observed but surprisingly little understood. Lewis,² who described the condition in soldiers, termed it a "vasovagal collapse," being impressed by the slow pulse so frequently seen, and by the supposed value of atropine in its therapy. Later studies demonstrated that atropine did prevent the slowing of the pulse but did not influence the collapse, and Lewis pointed out that the vagus nerve was therefore not vitally concerned in the phenomenon, which presumably then implicated the vasomotor system. It is, of course, largely to the credit of Weiss³ that a collapse syndrome was defined in which the vagus nerve is basically responsible. Despite such

a clear separation of the two conditions, one continues to find references to the vagal origin of the so called "vasovagal syndrome," and to the necessity for atropine as a prophylactic or therapeutic measure.

The next major advance in the elucidation of the vasovagal syndrome, to which the term "primary shock" might also apply, was also made by Weiss.⁴⁻⁶ Although clinicians and physiologists described the phenomenon in vague terms of "vasomotor paralysis" or "splanchnic vasodilatation," Weiss was able to demonstrate that the locus of the circulatory disturbance is in the veins and venules, and possibly the capillaries, whereas the arterial tree shows, if anything, a vasoconstriction. In other words, the fall in blood pressure is due, not to generalized peripheral vasodilatation, which reduces the peripheral resistance to a degree where blood escapes from the arterial system so rapidly that a head of pressure cannot be maintained, but rather to the fact that the veins and venules dilate greatly and act as a reservoir for large amounts of blood. Venous pressure at the right auricle then falls, cardiac filling diminishes, and concomitantly, cardiac output and arterial blood pressure decrease. Later studies of a slightly different type (venous occlusion by ligature) indicate that the pooling of about a liter of blood is sufficient to induce symptoms of collapse.⁶

The experiments of Weiss involve the interaction of two factors: the upright posture on a tilting table, which reduces muscular activity in the dependent parts of the body, and the administration of small doses of sodium nitrite. Either procedure alone usually produces no symptoms, but the combination regularly induces the typical syndrome in which "the primary change consists in tachycardia, small arterial pulse pressure, with small pulse volume (thready pulse), fall in the venous pressure, and arteriolar vasoconstriction." Studying the cause of the fall in venous pressure, Weiss and his collaborators found that nitrites cause a profound diminution in the tone of the venous system, so that, to raise the venous pressure in a limb to a given level, far more blood would have to flow into the vessels of the part. The rate of inflow is diminished, indicating the presence of arteriolar vasoconstriction. In the absence of the muscular massage that normally promotes the emptying of veins toward the heart, such dilatable veins could not resist the force of gravity which tends to pool blood in dependent parts.

Inquiries emphasize the fact that therapeutic or prophylactic measures must be taken primarily to increase venous pressure. Restoration to the horizontal position is always rapidly effective. Larger doses of nitrites can cause collapse, even in the horizontal position, and elevation of the lower

part of the body is presumably an effective therapy. The common vasoconstrictor drugs—epinephrine and Pitressin—are without value, and Pitressin probably facilitates collapse.^{7, 8} Paredrinol (*a-n*-dimethyl-*p*-hydroxyphenethylamine) was shown to be distinctly useful in a number of cases, either preventing collapse completely or greatly delaying its onset.⁹ This substance, first studied by Rein,¹⁰ has a more active vasoconstrictor influence on the venous than the arterial portions of the circulatory system.^{12, 13}

Search is now being made for situations in which a similar loss of venous tone forms the basis for other shocklike phenomena. Paredrinol appears to be effective in severe cases of postural hypotension with syncope and is occasionally of value in the hypotension associated with acute infectious diseases. A decreased venous tone and the presence of postural syncope have been reported during the convalescent stages of such illnesses.¹³⁻¹⁵ Careful studies by Ebert and Stead,¹⁶ however, reveal that this is not the only, perhaps not the paramount, circulatory disturbance during the acute stage of infectious diseases, since elevation of the feet and intravenous infusions of whole blood, plasma or 10 per cent glucose fail to produce improvement in the circulation. The patients in whom these procedures were tried were virtually moribund, and in certain cases, elevation in blood pressure was evoked. It must also be recalled that Altschule and Gilligan¹⁷ and others¹⁸ have demonstrated how very quickly even large transfusions are compensated for by vasodilatation that includes arteriole and venuoles, so that only temporary changes in blood pressure are to be expected.

Denny-Brown and Russell¹⁹ offer evidence, which cannot be said to be completely convincing, that pooling in the venous system is responsible for the initial fall in blood pressure after concussion caused by blows on the head. They suggest "vasomotor paralysis" or stimulation of the glossopharyngeal-vagal mechanism as the responsible factor. These suggestions demonstrate how little is yet known of the pathologic physiology of the veins. From Franklin's²⁰ review of the data up to 1937, it appears that the veins of the abdomen are normally innervated by fibers of the sympathetic system; that section of these nerves dilates the veins, whereas stimulation of the peripheral stump of the nerve constricts them; that after ergotoxine to paralyze sympathetic hormonal effects, stimulation of the same nerve causes venous dilatation; and that the dilatation of the veins produced by tapping of the vein or the abdomen is a local effect not dependent on the central nervous system. At that time, Franklin could not find any circumstances in which reflex venous

dilatation had been demonstrated without question. The value of continuation of the studies inaugurated by Weiss is obvious.

RENAL BLOOD FLOW IN HUMAN HYPERTENSION

The method of Diodrast clearance, which Smith and his colleagues²¹ have shown to measure blood flow through the excretory portions of the kidney, has now been applied to a study of blood flow in human hypertension. These studies indicate clearly that a reduction in renal blood flow, which occurs in so-called "essential hypertension" may be of extreme degree.²²⁻²⁴ The administration of a pyrogenic substance (inulin), which causes an increase in renal blood flow in the normal kidney, has the same effect in the hypertensive kidney. Such findings are consistent with the view that in such kidneys, a reversible vasoconstriction exists, perhaps in the efferent vessels of the glomerulus. The same studies detect a variable decrease in the total excretory mass, denoting a destruction of kidney substance. In no case of essential hypertension was it possible to detect any difference between the degree of involvement of the two kidneys.²⁵ In a study of 5 patients with hypertension associated with unilateral renal damage, a marked difference in the blood flow in the two kidneys was detected, although the blood flow in the supposedly normal kidney was also below normal.²⁶ Removal of the diseased kidney was followed in all 5 cases by an increase in the blood flow in the remaining kidney. A significant fall in blood pressure took place in 3 of the 5 patients, but in none was a normal blood pressure re-established, although in 3 cases a normal blood flow was established in the remaining kidney.

An unexpected finding is that in the hypertension of toxemia of pregnancy, in the pretoxemic state, or in the hypertensive state following toxemia of pregnancy, no indication of diminution in renal blood flow can be demonstrated.²⁷⁻³⁰ Some evidence of increased blood flow is occasionally made out. These experiments cast certain grave doubts on any theory that explains all types of hypertension in man on the basis of renal ischemia. They do not, however, necessarily indicate that the hypothesis of a renal origin of hypertension need be abandoned. Corcoran and Page³¹ call attention to the fact that dogs showing hypertension in response to renal arterial obstruction may also give normal Diodrast clearances. The persistence of experimental renal hypertension in the absence of renal ischemia is consistent with their view that intrarenal reduction of pulse pressure, rather than ischemia, may be the effective cause of experimental renal hypertension. The renal origin of the hypertension of toxemias of

pregnancy therefore still remains a possibility. The diminished renal blood flow in essential hypertension, of course, is also consistent with the renal origin of the disease, but there remains the possibility that the reversible vasoconstriction observed is only the renal manifestation of the generalized vasoconstriction that maintains the hypertension.

INDUCTION OF VENTRICULAR FIBRILLATION

In man, ventricular fibrillation most frequently occurs as a sequel to an idioventricular tachy-systolic episode. Several important factors in its origin have been pointed out, such as the facilitating influence of adrenalin or sympathetic stimulation in light chloroform anesthesia or acute benzol poisoning and that of intraventricular block in the fibrillation of heart disease. Recently, Wiggers and his co-workers³²⁻³⁵ have analyzed in some detail the fibrillation occurring after single intense electrical shocks, after a series of induction shocks, and after anodal and cathodal polarization. In all these circumstances, it appears that a sequence of ventricular extrasystoles is set up, comprising in fact a short run of ventricular tachycardia in which all beats originate from the same focus. These impulses are at first conducted radially away from the point of origin and involve the entire ventricular mass. Each successive beat arises after a slightly reduced interval, and is conducted away from its site of origin. After a very few beats, one wave is found to be traveling only a centimeter or two behind the previous beat. At this point, two alternative events may occur: the next beat meets refractory tissue in all directions and is blocked completely, or block is irregular, and some avenues are still open to it. In the latter event, the stage is set for the establishment of so called "circus motion," which constitutes ventricular fibrillation.

The intense single shock or the polarizing currents appear to create the initial series of tachysystoles by causing failure of the normal accommodation to internal or external stimuli, but obviously any tachysystoles may ultimately lead to ventricular fibrillation. Whether or not ventricular fibrillation develops must depend in the main on the state of the intracardiac conduction system. Any factors favoring the irregular development of intraventricular block must promote fibrillation, as Davis and Sprague³⁶ pointed out in 1928. Wiggers's theory seems to be essentially the same as that proposed by Nahum and Hoff³⁷ to account for the development of fibrillation by an intravenous injection of potassium chloride. These authors were impressed by the fact that fibrillation did not take place if marked reduction of cardiac rhyth-

micity occurred concomitantly with the development of intraventricular block, whereas fibrillation did occur if rhythmicity were maintained while block developed. They concluded that for the genesis of ventricular fibrillation two factors were essential: the presence of foci of automaticity in the ventricles, and intraventricular block. It is apparent that in the presence of an automatic focus of increasing rhythmicity, fibrillation may begin because of physiologic blocking in an otherwise normal heart. On the other hand, a heart in which damage to the myocardium has produced regions of varying block should be more susceptible to fibrillation than a normal heart. In a preliminary communication, Harris et al³⁸ have extended their observations to include the fibrillation following occlusion of a coronary artery, and find a similar mechanism operating.

COAGULATION OF BLOOD

The so called "classic theory" continues to retain validity as the basic explanation of blood coagulation. The reaction in two stages of prothrombin, calcium and thromboplastin to form thrombin, and of thrombin and fibrinogen to form fibrin, has been the subject of repeated examination. Although no insurmountable obstacle to its continued acceptance has as yet appeared, much has been learned of the nature and source of the individual factors, and of their role in the various hemorrhagic diseases. Excellent reviews by Quick³⁹ and Howell^{40, 41} deal particularly with this problem.

The role of vitamin K in the production of prothrombin is now well recognized and needs no further review. An equally promising field, now in the stage of active development, deals with the nature of the thromboplastic substance. The recent significant contributions in this field are largely those of Taylor and his co-workers.

These studies began with the observation of Patek and Taylor⁴² that from the blood plasma of normal human subjects there can be precipitated by dilution and acidification a globulin fraction that contains a clot promoting substance for hemophilic blood. The material is active while fresh, or after drying in a vacuum. The same treatment of hemophilic blood yielded a precipitate that had little or no clot-promoting ability. Tested in a calcium fibrinogen system, precipitates from both normal and hemophilic blood had equal prothrombin activity.

Later studies⁴³⁻⁴⁵ demonstrated that both prothrombin and fibrinogen could be removed from this globulin substance without impairing the clot-promoting faculty for hemophilic blood. Further fractionation then demonstrated that all this clot-

promoting activity could be found in a euglobulin fraction. From these studies and from those of Howell,^{40, 41} it becomes clear that the essential defect in hemophilia is the absence or deficiency of a euglobulin fraction of the plasma, which, in terms of the classic theory, may be designated as "plasma thromboplastin."

This observation immediately directs attention to the blood platelets. Quick³⁹ observes:

Thromboplastin is widely distributed in the body as an intracellular substance. In the blood it occurs locked up in the platelets and perhaps is present also in the leukocytes. Certain tissues, notably the brain, lungs, and thymus, are particularly rich in thromboplastin. It apparently never occurs free, but is liberated whenever tissue cells are injured or ruptured. *In blood uncontaminated by tissue juices, the thromboplastin is liberated solely by the platelets. The liberation of thromboplastin by the platelets, therefore, appears to be the prime factor in determining the clotting time of blood obtained by venipuncture.* [italics mine].

It is, of course, well known that no quantitative change in the platelets exists in hemophilia, and the reviews of the question of qualitative changes by Quick and Howell yield no very convincing evidence. It is equally recognized that great reduction in platelets may occur in thrombocytopenic purpura without change in the coagulation time of venipuncture blood. In view of these and other doubts cast on the platelet origin of plasma thromboplastin, Lozner and Taylor⁴⁶ have recently completed a most interesting study on the effect of foreign substance on blood coagulation.

The orientation of their work may be described most effectively by direct quotation:

It has been known for many years that the coagulation time of blood taken in paraffin tubes is much longer than that of blood taken in glass tubes. The explanation usually afforded is that the glass, acting as a foreign surface, destroys the platelets at a more rapid rate than occurs in the presence of paraffin. The increased amount of thromboplastin so liberated is then considered to be responsible for the shorter coagulation time in glass vessels. Nolf has criticized this explanation. He states that his experimental data indicate that cell- and platelet-free plasma already contains all the factors necessary for blood coagulation. He believes that the initiation of coagulation is the result of direct modification of one or more of the constituents of cell-free plasma by contact with a foreign surface such as glass.

Four types of experiments were carried out, normal human blood obtained by clean venipuncture being used. In the first series, normal human plasma was employed without the addition of anti-coagulants. The blood was drawn in an oiled syringe and transferred to a Lusteroid (a synthetic plastic) tube. Centrifugation at 4200 revolutions per minute for ten minutes gave a clear plasma with a platelet count of 8000 per cubic millimeter,

essentially "platelet free." The plasma was then transferred to tubes of different materials in collodion pipettes, and the coagulation times determined. This was 11 minutes in glass, 64 minutes in collodion, 44 minutes in paraffin, and 49 minutes in Lusteroid. Since the plasma was platelet free, it must be concluded that all the elements necessary for coagulation were present in the plasma at the time it was removed from the centrifuge, and that the accelerating effect of glass was not exerted on the platelets.

In the second series of experiments, blood was transferred into Lusteroid tubes containing citrate, and a platelet-rich plasma obtained by slow centrifugation. Samples were transferred to the four tubes and stored for an hour. No destruction of platelets was found in any of the tubes as determined by platelet counts at the beginning and end of the storage period. Nevertheless, when samples of the plasma were recalcified in Lusteroid, the plasma stored in glass showed a coagulation time of six minutes, whereas the coagulation times of the other plasmas were prolonged. When cell-free plasma was stored as described above and then recalcified in Lusteroid, the glass-stored plasma clotted in eleven minutes, whereas that stored in paraffin, collodion or Lusteroid clotted in from eleven to thirty-nine minutes. These experiments indicate that glass storage does not destroy platelets, but does bring about a change in citrated plasma, either platelet rich or platelet free, that promotes coagulation when calcium is added.

A third series of experiments demonstrated that storage in glass increases the clot-promoting activity of either cell-free or cell-rich plasma when added to hemophilic blood. Finally, it was found that the preparation of the globulin substance (Howell's plasma thromboplastin) in glass vessels yielded a product of far greater clot-promoting properties than that prepared in paraffin or collodion vessels.

The authors conclude:

The foregoing observations show that the effect of foreign surfaces on blood coagulation are [*sic*] essentially independent of the intact platelet. These studies indicate that the site of action of such surfaces is dependent upon a factor which is present in normal cell-free plasma, independent of prothrombin and fibrinogen associated with the euglobulin fraction of the protein and concerned with the clot-promoting activity of plasma for hemophilic blood [that is, plasma thromboplastin, according to Howell's nomenclature]. That this globulin substance might be derived from damaged platelets cannot be excluded by the present observations. However, it is present in cell-free plasma, and foreign surfaces have entirely similar effects, on platelet-free and platelet-rich plasma. The data presented clearly indicate that the effect of foreign surfaces is not accompanied by an increased lysis of the platelets prior to clot formation as heretofore assumed.

Taylor and Lozner tentatively offer Gortner and Briggs's⁴⁷ suggestion that glass activates thromboplastin by virtue of its surface electrical charge.

This evidence that all the necessary factors for clot formation are found in normal circulating plasma raises new and interesting problems. It seems to afford an explanation for the presence in circulating rabbit plasma of a clot-promoting factor observed by Parfentjev⁴⁸ and demonstrated by Taylor et al.^{49, 50} to be a true thrombin. It is possible that, in the rabbit at least, the reaction of prothrombin, calcium and plasma thromboplastin is a continuous one, and that small quantities of thrombin are constantly being formed. Why this thrombin does not react with fibrinogen to form fibrin remains a question, but its presence without clot formation indicates the presence of an anticoagulant. One should recall both the observation of Lozner, Joliffe and Taylor⁵¹ of a patient with a hemorrhagic diathesis, with prolonged clotting time associated with a circulating anticoagulant, and Quick's³⁹ belief that heparin is normally present, in combination with albumin, in circulating blood, where it exerts an anti-thrombin effect.

NEUROMUSCULAR TRANSMISSION

The recent work of Nachmansohn et al.^{52, 58} has introduced a decidedly new point of view into a subject that at times seemed to have degenerated into a controversy between proponents of the so-called "electrical" and "chemical" theories of neuromuscular transmission. These studies have in great measure concerned the discharge of the electric organs of certain fish,—notably, the torpedo, the ray and the electric eel,—in which the electric organ is composed essentially of modified muscular end plates arranged in series, all other muscular elements having disappeared in the evolution of the structure. In these organs, discharge caused by stimulation of the appropriate motor nerve is accompanied by the liberation of acetylcholine. The injection of acetylcholine produces an electrical discharge, and the previous injection of eserine increases and prolongs the discharge produced by nerve stimulation or by acetylcholine. Nachmansohn and his associates have also demonstrated the presence of a high concentration of acetylcholine esterase in the electric organ, a concentration that varies directly with the intensity of the electrical discharge.

Considering these facts together with the observations that acetylcholine esterase is present in all nervous tissue and that it is concentrated at the surface of the tissue rather than in the axoplasm, the authors come to the following conclusions:

acetylcholine participates in nerve transmission in all parts of the nervous system, and is not specifically limited to junctional tissues such as the synapse and the neuromuscular junction; and, in some fashion, the liberation of acetylcholine is responsible for the development of the electrical discharge that characterizes the physiologic activity of all nervous tissue and is recognized as a surface phenomenon.

In addition, these studies reveal the concentration at the surface of the axon of a high concentration of vitamin B₁, and suggest that this hormone is also implicated in the metabolism of acetylcholine. The hormone is essential for the metabolism of pyruvate, one stage of which yields acetate, and in the absence of vitamin B₁, the acetylation of choline to form acetylcholine is deficient. These observations therefore suggest that one of the essential biochemical lesions in the polyneuritis of vitamin B₁ deficiency is a diminished formation of acetylcholine and a consequent failure of nerve transmission.

A satisfactory schema of neuromuscular transmission can be constructed if, in addition to the above, the recent studies of Eccles and his co-workers^{50, 63} are considered. These investigators have for a number of years studied the electrical events occurring at the neuromuscular junction and have succeeded in recording potentials that appear to be derived from the motor end plate itself. They have shown that curarization diminishes the intensity of this potential, and that when the intensity decreases to less than 30 per cent of its normal value, failure of transmission occurs. End plate potentials show a slow decay, which permits summation of two successive potentials. If their combined height reaches 30 per cent or more of normal height, an impulse is set up in the muscle. Eserine antagonizes the action of curare by increasing the height of the end-plate potential.

There is therefore justification for the following theory of neuromuscular transmission: the impulse arriving at the end plate from the nerve liberates acetylcholine; the acetylcholine produces the end plate potential; and the end plate potential excites the muscle. There is no reason why a similar mechanism may not operate in transmission in the simple nerve fiber, with a repeated sequence of acetylcholine liberation, action current and excitation of adjacent tissue. The well known effects of action currents in stimulating surrounding tissue can be recalled. Recent studies of the effect of axon on axon⁶⁴ and muscle on its motor fiber⁶⁵ deserve attention.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28291*

PRESENTATION OF CASE

An eleven-year-old schoolgirl was admitted to the hospital because of pain "like a hammer blow" in the left flank, lower abdomen and thigh.

She had been in good health until nine months before entry, when there was a gradual onset of

forded slight relief. There was no history of significant trauma.

On examination the patient appeared well developed. The chest and abdomen were normal. There was right lumbar scoliosis, and some spinal rigidity, with tenderness to the left of the second lumbar vertebra. All reflexes were intact, and there were no sensory disturbances. Naffziger's¹ test caused pain to radiate around into the left lower quadrant and down the anterolateral aspect of the thigh to the knee.

The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,420,000 with 13.2 gm. hemoglobin, and a white-cell count of 9300 with 60 per cent polymorphonuclears. The blood Hinton reaction was negative. The urine was normal. A lumbar puncture gave clear fluid under an initial pressure equivalent to 100 mm. of water. Bilateral jugular compression caused a rise in pressure to 250 mm. in thirty seconds, with a fall to 160 mm. in one minute after release; there were normal oscillations with the respiratory cycles. The total protein of the spinal fluid was 34 mg. per 100 cc., and the gold-sol curve was 0011100000.

A roentgenogram of the spine showed marked curvature of the lower dorsal and lumbar vertebrae toward the right. The individual bones and joints appeared normal, except for a large, sharply defined defect in the pedicle of the second lumbar vertebra on the left (Fig. 1). The uninvolved anterior portion of the pedicle was increased in density.

On the seventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. MARIUS N. SMITH-PETERSEN: I do not know what a pain like a "hammer blow" refers to, or whether that was the onset of pain or not. If it were the onset of pain, it might be significant; if it were persistent pain of a throbbing character, it might also be important—this statement is not clear. The hammer-blow pain might have been caused by a fracture superimposed on underlying disease.

Later in the history, we have a statement to the effect that the onset of pain was gradual and that the pain was sharp and stabbing in character. From this statement we can conclude that the hammer-blow pain probably did not refer to a fracture superimposed on disease.

The distribution of pain was extensive: local pain in the left costovertebral angle, accompanied by radiation pain to the groin and to the anterolateral surface of the left thigh, as far as the

FIGURE 1.

attacks of sharp, stabbing pain, beginning in the left costovertebral angle and radiating both to the groin and anterolateral surface of the left thigh as far as the knee and to the left lower quadrant of the abdomen. These attacks were aggravated by straining, coughing, sneezing and other sudden motions. They usually appeared in the afternoon, occasionally at night, when the patient lay in bed, and lasted up to an hour. They tended to increase in severity and in frequency. Aspirin af-

*The cases published in the July 16 issue of the *Journal* were incorrectly numbered "28301" and "28302," instead of "28291" and "28292." To keep the correct total, this and the following case have been given the numbers of those omitted.

knee; and radiation pain in the left lower quadrant of the abdomen. The radiation pain described is consistent with a lesion involving the twelfth dorsal and the first and second, possibly the third, lumbar vertebrae. From the subjective pain, then, we can localize the lesion at the dorso-lumbar junction.

"The attacks were aggravated by straining, coughing, sneezing and other sudden motions." This is worth noting since the pain arising from a lesion impinging on the spinal canal would be aggravated by straining, coughing and sneezing.

"They [the attacks] usually appeared in the afternoon, occasionally at night, when the patient lay in bed, and lasted up to an hour." Freedom from pain in the morning can be explained on the basis that the patient got up rested and carried herself better than she did later on in the day when she became tired. The lateral curvature could have been aggravated, and secondary strain thrown on the site of the lesion. The pain could not have been extremely severe or could not have increased very much, because the patient was not brought to the hospital for nine months after the onset.

"There was no history of significant trauma." We have no right to suspect the presence of a fracture unless it were superimposed on an underlying diseased condition.

"All reflexes were intact, and there were no sensory disturbances." These findings point away from a lesion involving the spinal canal.

Naffziger's test aggravated the pain radiating to the left lower quadrant and to the thigh. In my opinion, this reaction does not help us in making a differential diagnosis.

The blood picture, including the white-cell and differential counts, is against an infection, such as osteomyelitis.

A lumbar puncture was done. The dynamics were normal, but the total protein (34 mg. per 100 cc.) was high for a child of 11, pointing to possible irritation of the meninges.

X-ray films showed a sharply defined lesion in the pedicle of the second lumbar vertebra on the left. The uninvolved anterior portion of the pedicle showed an apparent increase in density. The appearance is consistent with a cyst and with xanthoma. Giant-cell tumor should be mentioned, but the patient is too young and I have never seen a giant-cell lesion in this location. Tuberculosis must also be mentioned, but I have never seen tuberculosis involving the pedicle. Hemangioma is my final alternative, but, again, I have never seen one in this region. Personally, I favor a diagnosis of cyst or of xanthoma.

DR. LAURENCE L. ROBBINS: I think I have seen this case before, so that it is not quite fair for me to

interpret the films. I should say that the important diagnostic point, so far as the radiologist is concerned, is the area of rarefaction with a rather sharp line of increased density around a portion of the margin. There is increased density in the pedicle, as described. I should not consider tuberculosis, and I do not believe that it is a hemangioma, because the usual appearance of hemangioma of the vertebra is more that of coarse striations.

DR. SMITH-PETERSEN: What would be your best guess?

DR. ROBBINS: I know the diagnosis, having seen the films before.

DR. TRACY B. MALLORY: I think it is fair to say, however, that the X-ray Department did not suggest the correct diagnosis preoperatively.

Would anyone care to make any other suggestion?

DR. ERNEST M. DALAND: How do you rule out Ewing's tumor?

DR. SMITH-PETERSEN: I cannot rule it out.

A PHYSICIAN: Is the scoliosis presumably entirely secondary?

DR. SMITH-PETERSEN: I think so. One cannot depend on the parents' observation. Time and again, one observes extreme scoliosis, just discovered. In this case, I think it is fair to say that it came on in response to pain.

DR. CHANNING C. SIMMONS: You have said that a giant-cell tumor is rarely seen at that age. I have been thinking it over, and I can think of 4 patients who were roughly under fourteen. If you were to ask me for the exact ages, I could not give them.

DR. SMITH-PETERSEN: I had a patient at the age of twelve who, according to the pathologists, had a giant-cell tumor; as time went on, the diagnosis was changed to cyst.

DR. FULLER ALBRIGHT: One sees giant-cell tumors in children with hyperparathyroidism.

CLINICAL DIAGNOSIS

Extradural tumor, at level of second lumbar vertebra.

DR. SMITH-PETERSEN'S DIAGNOSIS

Cyst, involving pedicle of second lumbar vertebra.

ANATOMICAL DIAGNOSIS

Osteoid osteoma of second lumbar vertebra.

PATHOLOGICAL DISCUSSION

DR. MALLORY: This patient was operated on by Dr. W. J. Mixter. The only preoperative diagnosis recorded is "tumor of the spine." They did

not commit themselves any closer. An evident tumor mass, consisting of obviously abnormal, rather soft bone, was found in the lamina of the second lumbar vertebra, and that, together with the transverse process, which was slightly involved, was removed. Microscopic examination showed a focus of intertwined osteoid trabeculae separated from each other by narrow bands of relatively acellular fibrous tissue. At the periphery of the lesion, the cortical bone was denser than normal. The picture is very characteristic of what Jaffe and Lichtenstein² have described as osteoid osteoma.

DR. SMITH-PETERSEN: As a matter of fact, Dr. C. B. Larson made that diagnosis. I talked this case over with him, and he suggested "osteoid osteoma."

DR. LARSON: It is unusual to find a punched-out lesion without more sclerosis of the bone around it.

DR. JACOB LERMAN: Did it involve the spinal canal?

DR. MALLORY: The operative note does not make that clear.

DR. SMITH-PETERSEN: It must have infringed on the spinal canal.

CASE 28292

PRESENTATION OF CASE

First admission. A forty-nine-year-old white widowed painter was admitted complaining of inability to see to either side.

The patient was well until one year before admission, at which time he developed colicky pains in his abdomen, with nausea and vomiting in the morning. At the same time, he had gripping pains in both legs. There was also a feeling of weakness and lassitude. Some teeth were extracted, and a "lead line" of the gums was noted. Following this, he improved, although he continued to feel weak. Ten months before admission a physician examined his eyes; although the patient had no complaints, he was advised to wear glasses. The visual fields were normal. Three months prior to entry he noticed dimness in the left visual field of his left eye. This gradually increased. Three weeks before entry, it was thought that his left frontal sinus was at fault, and it was operated on. Immediately following the operation, the patient noted that he could not see well to the right side with his right eye. A few days after this,

his nausea and vomiting recurred. He had had rare headaches, but these had not increased during the last two years.

The patient had been a painter for eighteen years. One brother had diabetes. Seventeen years before entry, the patient had been kicked on the forehead by a horse, and five stitches had been taken; he had had no residual symptoms.

Physical examination showed a well-developed and well-nourished man in no distress. All but two lower teeth were missing. There was a slight postnasal discharge. Examination of the chest was negative. The remainder of the general physical examination was negative. Neurologic examination showed normal mentality. The fundi were normal except for slightly dilated vessels. The visual fields showed bitemporal hemianopsia. External ocular movements were normal, and there was no nystagmus. The pupils reacted normally to light and accommodation. The remaining cranial nerves were negative. The reflexes were normal and equal on both sides. There were no other neurologic abnormalities.

The blood pressure was 155 systolic, 100 diastolic. The temperature was 97.4°F., the pulse 80, and the respirations 20.

The urine showed a specific gravity of 1.012 on one occasion and 1.008 on another, but was otherwise normal. The blood showed a red-cell count of 4,200,000 with 60 per cent hemoglobin, and a white-cell count of 6800 with 72 per cent polymorphonuclears. A lumbar puncture showed an initial pressure of 175 mm. of water, which rose to 350 mm. with jugular compression on either side and fell normally to 180 mm. After withdrawal of 10 cc. of fluid, the pressure was 120 mm. The fluid contained 1 lymphocyte per cubic millimeter and 49 mg. of protein and 70 mg. of sugar per 100 cc. The gold-sol curve was 0011100000. The spinal-fluid Wassermann reaction was negative. A blood Hinton reaction was negative.

X-ray films of the skull showed no evidence of increased intracranial pressure. The pineal body was not definitely calcified. The sella turcica was quite abnormal in size and shape: it was greatly enlarged; the posterior clinoid processes were displaced backward, and the one on the right showed evidence of erosion and decalcification; and the right floor of the sella showed evidence of erosion. There was increase in the size of the lower jaw, and all the bones of the skull appeared slightly thicker and denser than normal. The hands showed increased length of all the bones and slight tufting of the terminal phalanges. The bones of the feet were abnormally large.

A course of deep x-ray therapy was given over the pituitary gland: 800 r to the left sella, 800 r to

the right, and 600 r to both the anterior and posterior portions of the skull. After the third treatment, the patient was subjectively much improved and noticed a clearing of his visual fields. After his full course of therapy, however, visual-field determinations showed that there were still bilateral defects. On the thirty-first hospital day, an operation was performed. Between the optic nerves, which were definitely separated, was a bulging, blue-gray tumor, evidently arising in the pituitary fossa. It was explored with a needle, and about 5 cc. of brown fluid removed. The capsule was then incised, and a considerable amount of tumor curetted out. The sac seemed to be completely emptied but could not be removed because of the presence of large vessels. Pathological examination of this specimen revealed dense connective tissue containing large thin-walled vascular channels, but no epithelium. The patient improved rapidly following the operation and was discharged on the forty-ninth hospital day, with instructions to return after two weeks for visual-field examinations.

Second admission (six years later). The patient was not re-examined until one year after he was discharged, at which time visual fields showed moderate generalized narrowing on both sides. He had had no complaints until two years before his second admission, when he began to see dark spots in front of his eyes, associated with dyspnea, at the same time feeling as though he would drop. Six months before admission, he was unable to sleep well. Two months later, he had an attack of "flu," characterized by weakness, malaise and fever, and remained in bed for three weeks. Following this, he was weak and fatigued; his speech became slow, and anorexia severe. Intermittent nausea and vomiting recurred. There was no evidence of blood in the vomitus, and the vomiting was not projectile in type; it usually occurred immediately after a meal. The patient had had no headaches or convulsions. During the previous three months, he had noticed an increased sensibility to cold weather and generalized muscle aches. Two months before entry, visual-field determinations in the Eye Clinic showed marked narrowing on all sides, especially in the upper temporal fields. The visual acuity was 20/20 in the right eye, and 20/30 in the left. The fundi showed slight atrophy of the nasal side of each disk. Six weeks before admission, the patient entered the Thyroid Clinic, where a basal metabolic rate of -21 per cent was found. His skin was dry, and there was slight myxedema of the neck and face. A slowing of his mental processes was noted. Thyroid therapy was begun. During the previous two

years, his weight had dropped from 210 to 175 pounds.

Physical examination on entry showed a slightly obese, well-developed and well-nourished man in no distress. The skin was pale and soft, but not dry or brittle. The hair was soft and silky, and the hair over the body was decreased in amount. The face was puffy. Examination of the fundi was essentially negative. The visual acuity was 20/20 in each eye. The visual fields showed only slight bitemporal narrowing, more marked on the right. The tongue deviated slightly to the right. Examination of the chest was negative. The abdomen was normal. There were no other pertinent findings.

The blood pressure was 140 systolic, 88 diastolic, lying down; 138 systolic, 92 diastolic, sitting; and 118 systolic, 92 diastolic, standing. The temperature was 98.6°F., the pulse 72, and the respirations 20.

Urine examination showed a specific gravity of 1.018; there were no abnormal findings. The blood showed a red-cell count of 4,100,000 with 65 per cent hemoglobin, and a white-cell count of 8000 with 41 per cent polymorphonuclears, 11 per cent large lymphocytes, 27 per cent small lymphocytes, 10 per cent mononuclears, 7 per cent eosinophils, 2 per cent basophils and 2 per cent unidentified cells. The smear showed slight achromia. The nonprotein nitrogen of the serum was 27 mg. per 100 cc., the chlorides 96 milliequiv. and the sodium 130 milliequiv. per liter, and the cholesterol 170 mg. per 100 cc. A sugar-tolerance test showed 87 mg. per 100 cc., fasting; 121 mg., in half an hour; 84 mg., in one hour; 98 mg., in two hours; and 112 mg., in three and a half hours. A blood Hinton reaction was negative. The basal metabolic rate was -22 per cent. A stool examination was guaiac negative. An electrocardiogram showed rather low voltage of the QRS complexes and T waves.

X-ray films of the skull showed marked enlargement of the sella, with marked decalcification of the dorsum sellae and posterior clinoid processes. There was no evidence of increased intracranial pressure. Films of the hands showed that all the bones were rather heavy; there was questionable tufting of the terminal phalanx of the fourth right finger. The chest films showed multiple areas of calcification scattered throughout both lung fields, particularly marked in both apical fields. The heart was normal.

The patient was given a high-salt diet and salt in gelatin capsules. Progressive improvement was obvious subjectively and objectively, and within twenty-four hours, his weakness and malaise had diminished considerably. He was discharged on the thirty-second hospital day.

Final admission (nine months later). The patient was seen one month after discharge, at which time his improvement had continued. A serum sodium at that time was 131 milliequiv. per liter, a potassium 3.8 milliequiv. and a total fixed base 139 milliequiv. Four months before re-entry, he developed general malaise, weakness, lassitude and aching in the joints. Following this, he had occasional fainting spells preceded by a feeling of increased weakness and perspiration. Many of these impending attacks were warded off by absolute rest and sugar by mouth. Two weeks before admission, on closing his right eye, he noticed that the temporal half of his left visual field was blind. He had no other complaints. He had gained 10 pounds in weight during the previous four months.

Physical examination showed a well-developed and dry-nourished man in no distress. The skin was dry, pale, parchmentlike and cold. The hair of the scalp and pubic regions was rather scanty. There was no bulging about the craniotomy scar. Examination of the chest was negative. The abdomen was normal. The fingers were enlarged. The testicles were somewhat smaller than normal. Neurologic examination showed that the patient was intelligent and co-operative. His speech was slow. The pupils were equal and active. External ocular movements were full, without nystagmus. The fundi were normal. Visual-field determinations showed a left temporal hemianopsia and dimness in the right temporal field. Visual acuity was 20/20 in the right eye, and 20/50 in the left. The remaining cranial nerves were normal. Motor and sensory examinations were negative except for slight impairment of the vibratory sense over the left foot and ankle.

The blood pressure was 150 systolic, 105 diastolic. The temperature was 98.6°F., the pulse 70, and the respirations 20.

Examination of the urine was negative. The blood showed a red-cell count of 4,850,000 with 75 per cent hemoglobin, and a white-cell count of 6100 with 45 per cent polymorphonuclears, 50 per cent lymphocytes, 2 per cent mononuclears and 3 per cent eosinophils. A blood Hinton reaction was negative. The fasting blood cholesterol was 180 mg. per 100 cc. The serum sodium was 132 milliequiv. per liter, and the total fixed base 141 milliequiv. A lumbar puncture showed normal pressure and normal dynamics. The fluid was clear and contained only 2 lymphocytes per cubic millimeter. The total protein was 93 mg. per 100 cc., and the sugar 59 mg.; the gold-sol curve was 0001110000.

X-ray films of the chest showed no change since the previous examination. Those of the skull were essentially the same.

On the twentieth hospital day, an insulin-tolerance test was done following a dose of 6 units of insulin; the blood-sugar levels at twenty, thirty, forty-five, sixty, ninety and one hundred and twenty minutes were 81, 58, 62, 68, 83 and 93 mg. per 100 cc., respectively. The corresponding blood pressures were as follows: 150 systolic, 100 diastolic; 130 systolic, 90 diastolic; 104 systolic, 70 diastolic; 110 systolic, 76 diastolic; 120 systolic, 80 diastolic; 136 systolic, 30 diastolic; and 136 systolic, 98 diastolic. A course of x-ray therapy was given, which included 1200 r to each of four portals. Following this, the patient's condition was essentially unchanged. On the thirty-fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD C. REIFENSTEIN, JR.: This is a very interesting case history. Let us retrace the involved course of events from the time that the patient became ill one year before his first admission to the hospital, which was about seven years before his second operation.

The first episode described in the history was an acute attack of abdominal colic, nausea, vomiting, gripping pains in the legs, weakness and lassitude. Such symptoms in a man who has been a painter for eighteen years and who is found to have a lead line of the gums indicate an acute attack of lead poisoning. The pains in the legs were probably manifestations of peripheral neuritis, which is not uncommonly seen in plumbism. It is interesting that the patient recovered from this neuritis without exhibiting a paralysis of the most used muscles of the legs, which is frequently encountered in acute intoxication with lead. It seems to me most unlikely that the lead poisoning had anything to do with the events that followed.

Nine months later the patient developed his next symptom: dimness in the left visual field of the left eye. The first thought that occurs to one is that the eye symptoms were related to the attack of lead poisoning and, hence, that the patient was developing an optic neuritis. The recurrence of nausea and vomiting shortly afterward also calls to mind the nausea and vomiting that were present during the attack of plumbism. However, nausea and vomiting do not usually present themselves as symptoms of plumbism in the absence of colic. Although it has been observed frequently that patients who have a considerable deposit of lead in their bones are apt to develop symptoms of acute intoxication with lead during a severe or protracted illness, in the present case, the patient, at the time of the recurrence of the nausea and vomiting, did not seem to have been sufficiently ill to have induced such a recurrence of

plumbism. Furthermore, the lack of other manifestations of lead poisoning and, particularly, peripheral neuritis at this time makes this interpretation doubtful. The demonstration of normal optic disks and bitemporal hemianopsia and the infrequency of the headaches help us to eliminate the question of lead intoxication from further consideration.

The finding of bitemporal hemianopsia immediately suggests an intracranial lesion, which provides a more likely explanation for the occurrence of nausea and vomiting. The slightly dilated retinal vessels, the slightly increased cerebrospinal-fluid pressure, the slightly increased cerebrospinal-fluid protein in the absence of cells, and the weak Type II gold-sol reaction are consistent with this interpretation. Furthermore, the bitemporal hemianopsia serves to localize the lesion as impinging on the optic chiasm. The x-ray evidence of a greatly enlarged sella turcica, with backward displacement of the posterior clinoid processes and erosion of the one on the right and the right floor of the sella, makes the picture complete. The clinical diagnosis of an intracranial lesion in the region of the pituitary gland warranted a trial of x-radiation therapy. When this proved ineffective, operation was indicated in an effort to protect the eyesight. The demonstration of the tumor mass at operation supplied the final proof of the correctness of the clinical diagnosis.

The major diagnostic problem in this case is the nature of the tumor mass that was found at operation. Before considering this, however, let us follow the subsequent course of the patient. For four years after the first operation, the patient was relatively free from symptoms. It is therefore reasonable to assume that the tumor mass, which seemed to be arising in the pituitary fossa, had not, up to that time, destroyed enough of the pituitary gland to interfere seriously with its function.

Two years before the second operation (four years after the first operation), however, a new sequence of events appeared. Not only did the visual symptoms become worse, suggesting that the tumor mass was again causing pressure on the optic chiasm, but, in addition, the patient developed increasing signs of insufficient function of the anterior pituitary gland. From a clinical point of view, the patient began to exhibit a considerable degree of so-called "panhypopituitarism"—that is, underfunction of all the elements of the anterior pituitary gland. There was evidence of inadequate function of the adrenal cortex: weakness, malaise and fatigue; Addisonian crises, with anorexia, nausea and vomiting; a loss of 35 pounds of weight; slight fall in blood pressure (from 155 systolic, 100 diastolic, on the first admission to 140

systolic, 88 diastolic); low serum sodium, chloride and total base values; and clinical improvement with a high-salt intake. There was also evidence of underfunction of the thyroid gland: increased sensibility to cold; dry, pale and soft skin; myxedema of the face and the neck; poor myocardial tone; generalized muscular aches; slowness of the mental processes; and a diminished metabolic rate. The fact that the basal metabolic rate on the second admission to the hospital was still -22 per cent in spite of thyroid therapy, which had been started six weeks before (and presumably was continued), suggests that the patient was not suffering from true myxedema (which would have responded by then), but rather from hypofunction of the thyroid gland secondary to underfunction of the anterior pituitary gland (which often fails to respond adequately to the usual thyroid therapy).¹ There was some evidence, furthermore, that the gonads were underfunctioning: a decrease in the amount of body hair; and testes somewhat smaller than normal. The glucose-tolerance test revealed increased tolerance: that is, the patient was hyperglycemia resistant. This finding is consistent with panhypopituitarism.² In spite of a high-salt intake and thyroid therapy, the patient began to have attacks of faintness associated with increased weakness and perspiration. These attacks were probably hypoglycemic attacks, since patients with panhypopituitarism are subject to such episodes, and since the attacks were controlled by the ingestion of sugar. There is no definite statement in the history that the patient was still receiving thyroid medication, but if so, this therapy may have induced the hypoglycemic attacks. We have seen several similar patients in whom this occurred. Thyroid medication also frequently induces Addisonian crises in these patients.

All these data make a strong case for the existence of a state of panhypopituitarism during this period. The one disturbing feature is the result of the insulin-tolerance test, which was normal. One would expect in panhypopituitarism to have hypoglycemia unresponsiveness—that is, inability to raise the blood-sugar level after an insulin-induced hypoglycemia. Furthermore, a full dose of insulin (0.1 unit per kilogram of ideal body weight) was given without any reaction, whereas patients with panhypopituitarism are so sensitive to an insulin-induced hypoglycemia that it is customary to give only a half to a third of the calculated dose of insulin to avoid reactions. In thus attaching significance to the insulin-tolerance test, we are assuming that the patient was properly prepared for the test by being placed on a diet containing at least 300 gm. of carbohydrate for at least three days prior to the test, and that he was

fasting for exactly twelve hours before the test was begun. If these conditions were not observed, the results of the test must be discarded.

It is unfortunate that we do not have available the results of 17-ketosteroid assays in this patient. This test measures the excretory products of the adrenal glands and the testes.³ In panhypopituitarism, the levels are almost invariably less than 05 mg. of steroid per twenty-four hours—that is, for practical purposes, negative. If we accept as valid the results of the insulin tolerance test, we must assume that some normal anterior pituitary gland tissue was still present and, therefore, that the 17-ketosteroids would not be negative, although they undoubtedly would be low, perhaps about 2 to 3 mg. per twenty four hours.

The increase in visual disturbance with atrophy of the nasal side of each disk, along with the gradual onset of some degree of pituitary underfunction, indicates that the tumor mass was again causing pressure on the optic chiasm. This is substantiated by the definite increase in the spinal fluid protein level. Since x-ray therapy was again ineffective, the only recourse was to attempt to remove the tumor surgically, in the hope of saving the eyesight.

Let us now consider what lesions may cause pressure on the optic chiasm. In order of frequency are found an adenoma of the pituitary gland, a so-called "suprasellar cyst" or *craniopharyngioma* and, finally, a lesion such as a glioma of the chiasm, a meningioma arising from the floor of the third ventricle, a tumor such as a chordoma or a cholesteatoma, or even a chronic circumscribed arachnoiditis. The chiasm is also occasionally compressed by one or both sides by an aneurysm or varicose dilatation of one or both carotid arteries. However, since bitemporal hemianopsia was present in the case under discussion, and since this disturbance rarely occurs except with pituitary adenomas or suprasellar cysts, we can limit our discussion to these two types of lesions.

There are three types of anterior pituitary adenomas: the eosinophil (acidophil), the chromophobe and the basophil, corresponding to the three types of cells found in the gland. The basophil adenomas are extremely rare, and never attain an appreciable size; therefore, in view of the x-ray evidence of a large lesion and the findings at the first operation we can eliminate this type of adenoma from further consideration.

Eosinophil adenoma is a tumor of hormone-producing cells and it thus accompanied by evidence of increased production of these hormones. These hormones would produce acromegaly in a man of forty nine. Are there any evidences of acromegaly in the patient under discussion? There is no history of an increase in the size of the jaw,

head, hands or feet. In x-ray films of the jaw and skull, the bones were interpreted as thicker and denser than normal, also the bones of the hands and feet were stated to be increased in length or "abnormally large." But large or long bones do not necessarily mean acromegaly unless there is a history of a recent increase in the size of these bones. The increased density of the bones can be explained just as well as the result of the chronic deposition of small amounts of lead in the bones over a period of eighteen years. At one time, it was thought that tufting of the terminal phalanges was diagnostic of acromegaly, we have since found this manifestation in many other conditions and now attach no particular significance to it. One of the findings on x-ray study that is of great help in diagnosing acromegaly is an increase in the anterior dimensions of the bodies of vertebrae, particularly the thoracic vertebrae. This is seen best in lateral films taken over the thoracolumbar spine. Unfortunately this film was not taken. As a result of this change, the patient is not able to bend over and touch his feet. This disability is not mentioned in the physical examination of our patient, and therefore may be assumed to be absent.

Another test of considerable diagnostic aid in acromegaly also was not done—the level of the phosphorus in the blood serum. Since patients with acromegaly are growing, the phosphorus level is almost always significantly elevated (4 to 6 mg per 100 cc) compared with the normal adult levels (about 3 to 4 mg).⁴ In fact, the level in acromegaly approaches that of a growing child.

Although the finding of hyperglycemia resistance is characteristic of panhypopituitarism, it may occur in acromegaly during the stage of so-called "compensatory hyperinsulinism." As a matter of fact, there is considerable variation in the type of curves obtained in the glucose tolerance, the glucose and insulin tolerance and the insulin tolerance tests in acromegaly, and the sugar curves are thus of no aid in the diagnosis of the condition.²

In view of the lack of history of an increase in size of the acral parts, and the absence of the x-ray films of the spine and of serum phosphorus values, all of which are commonly employed as diagnostic tests by the endocrine consultants of the Massachusetts General Hospital, we must conclude that acromegaly was not seriously considered by the physicians in charge of this patient during his stay in the hospital. Since all the reported x-ray findings are capable of another interpretation than acromegaly, I believe that this patient did not have an eosinophil adenoma. Furthermore, eosinophil adenomas are said to be sensitive to x-radiation, and the lack of response in our patient to two different courses of radiation is additional evidence

against this diagnosis. However, in dismissing an eosinophil adenoma, it must be pointed out that chromophobe adenomas have been reported that have had a small number of eosinophil cells in them.

Final pathological diagnosis, therefore, rests between a chromophobe adenoma of the anterior pituitary gland and a craniopharyngioma. This is a very difficult decision clinically, since either of these lesions could produce a picture in every way comparable to that of the patient under discussion. Neither of these lesions is hormone producing, so far as we know. The differentiation between them is at times of more than academic interest, particularly in early lesions, since it is occasionally possible to remove completely the craniopharyngioma and, thus, to cure the patient. Usually, however, all the cyst cannot be removed, and the danger of recurrence then exists. Successful complete removal of a chromophobe adenoma is very rare, and even in cases in which the tumor was presumably completely removed, the danger of recurrence is always present. In the patient under discussion, complete removal of the lesion was not possible; hence the differentiation between the two lesions is only of academic interest. As is apparent from the preceding discussion, recurrence of the lesion is of no help in the differential diagnosis.

The age of the patient at the time of the appearance of the tumor symptoms favors the diagnosis of chromophobe adenoma, which occurs oftenest in the third to fifth decade, and rarely before fifteen years. Although craniopharyngiomas are congenital tumors and may occur at any age, more than half of them appear in childhood, and the rate of frequency is much diminished in persons older than twenty years. The history of trauma to the head suggests a suprasellar cyst; however, the fact that the tumor did not become active until sixteen years after the accident makes this relation rather dubious.

From a statistical point of view, a chromophobe adenoma is about three times more likely than a craniopharyngioma. Of 2023 cases of intracranial tumors compiled by Cushing,⁵ pituitary adenomas comprise about 18 per cent and congenital tumors about 6 per cent.

The x-ray findings on the whole, favor a craniopharyngioma. A chromophobe adenoma of the pituitary gland typically causes great ballooning of the sella turcica, and only about a third of the cases exhibit erosion of the bony framework of the sella. Irregular erosion of the clinoid processes and the dorsum sellae is the usual finding in craniopharyngioma. In the patient in question, great enlargement of the sella was present, which favors a chromophobe tumor, but the erosion of the posterior clinoid processes and the floor of the sella

is more consistent with a suprasellar cyst. Unfortunately, the original films have been destroyed, so that we have to depend on the original interpretations without visualizing the films ourselves. No mention is made of calcification in the tumor area; this occurs in about three fourths of the cases of suprasellar cysts. We have to assume that it was not present. Since it is stated that the pineal body was not definitely calcified, it is likely that calcification was looked for in the region of the tumor.

The visual-field defects are stated to be more regular with a chromophobe adenoma than they are with a suprasellar cyst. In this patient, the lesions were quite consistently the same—bitemporal hemianopsia—and, hence, are in favor of adenoma.

The pathological findings at the first operation contribute some data to the differential diagnosis. The presence of a cyst favors a craniopharyngioma but does not exclude a chromophobe adenoma. Although the former is usually cystic, it may be solid; on the other hand, degeneration of an adenoma or hemorrhage into it is not uncommon. The brown fluid obtained by aspiration of the cyst might have occurred with either lesion. It would be interesting to know if crystals of cholesterol were found in this fluid, as might be expected in either lesion since they are both of epithelial origin. The presence of dense connective tissue and of large thin-walled vascular channels without epithelium suggests the stroma of a chromophobe adenoma; however, no strands of cells are described. We can more easily interpret these findings as the tough capsule of a suprasellar cyst; however, the epithelial lining of the cyst was not found.

In summing up the evidence, I believe that the most likely guess regarding the nature of the lesion is craniopharyngioma. The sequence of events was presumably as follows: an episode of acute lead poisoning; one year later, a craniopharyngioma became active and expanded to exert pressure on the optic chiasm, anterior pituitary function being adequate; first operation, a large part but not all the craniopharyngioma being removed; an interval of four years without symptoms; the craniopharyngioma again increased in size sufficiently to cause pressure on the optic chiasm and also destruction of most of the pituitary gland; an interval of two years before the second operation, with repeated evidence of underfunction of the anterior pituitary gland (panhypopituitarism) accompanied by attacks of hypoglycemia; and second operation, a large craniopharyngioma tumor mass being found that pressed on the optic chiasm and had destroyed most, *but not all*, of the pituitary gland. Some

normal anterior pituitary tissue was still present in all probability to account for the normal insulin-tolerance test.

CLINICAL DIAGNOSES

Pituitary cyst.
Panhypopituitarism, with marked adrenal insufficiency.
Circulatory failure (terminal).

DR. REIFENSTEIN'S DIAGNOSES

Craniopharyngioma, pressing on optic chiasm and having destroyed most of pituitary gland.
Panhypopituitarism.

ANATOMICAL DIAGNOSES

Pituitary adenoma, chromophobic type.
Atrophy of thyroid gland, parathyroid glands and testes.
Thrombosis of central adrenal vein, bilateral.
Infarction of adrenal medulla, bilateral.
Partial infarction of adrenal cortex, bilateral.
Pulmonary congestion and edema.
Pulmonary tuberculosis, healed, apical, bilateral.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This patient was operated on most reluctantly in a final desperate effort to save his vision, after it was evident that radiation therapy was accomplishing nothing. A cystic tumor was once again visualized in the region of the pituitary gland, and the contents of the cyst were aspirated. It was not possible to remove the tumor itself. Following operation the patient, as had been feared, did not do well. He developed an extensive facial erysipelas. This was gradually brought under control with sulfonamide therapy, and he seemed to have rounded the corner. Then, suddenly, he collapsed, developed acute pulmonary edema and died within a few hours.

The autopsy proved that Dr. Reifenstein was correct in his analysis of the endocrine abnormality. The hypophysis had been extensively destroyed by tumor, but a small remnant of the anterior lobe could be recognized. There was atrophy of the thyroid gland, which weighed only 9 gm. and showed, on microscopic examination, extensive fibrosis and lymphocytic infiltration. The parathyroid glands showed marked fatty replacement of the parenchyma, and the testes were moderately atrophic. The adrenal glands provided a surprise. Both showed fresh thrombosis of the central vein, with extensive venous infarction involving the entire medulla and inner third to half of the cortex. It seems very probable in retrospect that this bilateral adrenal infarction correlates with the sudden terminal change in the patient's condition.

The tumor of the hypophysis turns out to be a chromophobe adenoma, with extensive central degeneration and secondary cyst formation, rather than a true primary cystic tumor, such as a cranial myringioma. In checking back over the clinical record, I find that two determinations of the 17-ketosteroids were done but for some reason were not reported until after the patient's death. The figures of 2.0 and 2.8 mg. per twenty-four hours were obtained, which are exactly in the range that Dr. Reifenstein predicted.

NAVAL MEDICAL OFFICER PROCUREMENT

Perhaps, as intimated in a letter appearing elsewhere in this issue of the *Journal*, undue emphasis has been placed on the need for medical officers in the United States Army. The fact remains that the proportional need for physicians in the Navy is just as great.

The Office of Naval Officer Procurement is located at 150 Causeway Street, Boston, and those to whom this particular branch of the service appeals can be assured that commissions will be promptly granted to properly qualified physicians and that, ordinarily, calls to active duty will soon follow.

WILLIAM HENRY WELCH AND THE HEROIC AGE OF AMERICAN MEDICINE

Dr. William H. Welch led a life of so much activity that it would at first seem impossible to give even a running account of his many interests within the covers of a single volume. The skill of the Flexners,* however, has enabled them to present an excellent picture of one of the great figures in American medicine, a man who lived at a time when rapid evolution was taking place in medical thought. The authors have seen fit to describe this as "the heroic age of American medicine." One doubts if the term "heroic" is entirely satisfactory to describe a period such as that which Welch influenced.

That Welch should have been such a great figure in medicine is surprising in view of the fact that his early leanings were toward a career as a teacher of the classics. To be sure, his father, uncles, grandfather and great grandfather had all been country doctors in Connecticut. Medicine was indeed a tradition in the family, and the father naturally expected his gifted son to follow in his footsteps. Moreover, there was much in common between them, as one can judge by the delightful account of the country doctor given in this volume. Few pictures have been more exquisitely drawn than the description of the daily life of Welch's father, who was close to the people not only as their medical adviser but also as their true friend and counselor. The characteristic of doing so much work at night, moreover, was inherited by his more talented son.

Welch went to Yale, where he had a brilliant career both as a student and as a popular man. He was taken into Skull and Bones, the highest honor his fellow students could give him. Always interested in the classics, young Welch was tempted for years to teach school, but his father kept urging him to take a medical course and envisaged his son as his successor in country practice at Norfolk. Bending to his father's desire, Welch entered the College of Physicians and Surgeons in New

*Flexner, S., and Flexner, J. T. *William Henry Welch and the Heroic Age of American Medicine*. 539 pp. New York: The Viking Press, 1941.

York City in 1872. There, during his second year, he earned his first microscope for the best report on Seguin's lectures on nervous diseases. Because the lectures were held in the middle of Saturday afternoons, they were not well attended, but Welch considered them the best lectures in the curriculum and got his microscope, at that time something of a novelty. There were no laboratories for students in the medical school, and although a few professors used microscopes, it never occurred to them to pass their knowledge on to the undergraduates. Welch learned his first pathology from Delafield, but he soon found that if he wished to go beyond the simplest rudiments of histology, he must study abroad. After his graduation, in 1876, therefore, he took his first trip to Europe. He worked in the laboratories of Germany and France, being particularly impressed by the work of Cohnheim, who gave Welch his first chance to do experimental work. It was this work on edema that led to Welch's original paper on the subject, published in March, 1878, just after he returned to America.

Fired by an enthusiasm for laboratory investigation, he sought a post with Delafield in the College of Physicians and Surgeons. There was no space available, however, for Welch to set up a laboratory, and after a long series of negotiations, he finally obtained his desired room in Bellevue Hospital Medical College. He somehow acquired six antique microscopes and, by May, 1878, had six students working on pathologic specimens. Thus began scientific laboratory instruction for medical students in America, an accomplishment that will be regarded in the future as Welch's greatest contribution to medical advance in this country. Slowly, he increased his laboratory, and his fame extended beyond the borders of New York. Finally, the offer came to go to Baltimore, in connection with the founding of the Johns Hopkins Hospital and, subsequently, of the medical school. It was difficult for young Welch to leave New York, and his decision was certainly not made easier by the fact that his oldest and closest friend, Frederic S. Dennis, used every inducement to keep him there.

At last, the rift came, and the friendship was broken off by Dennis, much to Welch's grief. He was deeply disillusioned by the break and never again in his fifty years of association with great men did he allow anyone, either man or woman, to get close enough to him to hurt him as Dennis had done.

After another brief visit to Europe, Welch went to Baltimore, where he began his work in the fall of 1885. He was installed in a commodious two-story building quite in contrast to the so-called "laboratory" that he had occupied in New York. There, in October, 1891, Welch did an autopsy in which he showed that the tissues were filled with bubbles of gas. His bacteriologic examination led to the discovery of a new micro-organism, now known as *Clostridium welchii*. In addition to his own research, he stimulated investigation in others, and his laboratory became the center of activities in both pathology and bacteriology. The Johns Hopkins Hospital was opened in 1889, and Welch soon began to report on various diseases as they appeared in the hospital population. There was still no medical school, and to Welch fell the long and difficult task of leading the campaign for funds to establish one.

Whatever he said carried great weight, and so important had his decisions become, not only at Johns Hopkins but indeed in all medical schools in this country, that it was not strange that Mr. John D. Rockefeller and those nearest to him turned to Welch for advice in the spending of a part of the great Rockefeller fortune. Welch's name was known to Rockefeller not only for his work at Johns Hopkins but also as the founder and editor of the *Journal of Experimental Medicine*, the first scientific publication of its kind in this country. It was Welch, therefore, who laid the plans for the Rockefeller Institute for Medical Research, and his advice was widely accepted in many other fields. So great had his influence become that when two men were discussing what they would do if they had a million dollars for medical education, one instantly replied, "I should

give it to Dr. Welch." No one else in medicine in this country has ever established such a wide reputation for sound advice regarding matters of the teaching of medicine.

From his work in New York for the Rockefeller interests, he naturally spread into even wider fields and became a medical adviser to the whole nation. Few new projects were developed during the period of Welch's greatness that did not reflect, often directly, his influence. Later, he took his part in World War I, made an expedition to Japan and China and, at the age of seventy-five, established the Institute for the History of Medicine at Johns Hopkins as the culminating event in his long life.

Except for his early and close association with Dennis, Welch never had an intimate friend, and there was always about him an air of greatness, with a line of demarcation over which no one dared step. He was tolerant, pleasant and thoughtful, but always in a somewhat detached manner. Many people wished to read beneath the surface of his mind, but that was never possible. He was, however, sensitive in that he quickly reflected his environment. One notes his change of attitude toward his German teachers and friends after he had come to know American and English medicine better. He was not usually shaken, and it is said that on only one occasion, when he stepped into the post-mortem room of a soldiers' camp during the height of the influenza epidemic, did he ever appear startled and at a loss for a word. In spite of all the honors that were showered on him, he maintained his extreme modesty to the end, always going out of the way to be kind toward a junior colleague or even to a beginning student of medicine. His erudition was profound, for he could discourse on hundreds of topics in a fluent manner. He loved, nevertheless, the simple things of life, and nothing pleased him more than to join the motley crowd on a hot Sunday afternoon at the beach on Coney Island or to ride on the roller coasters with young people, with whom he immediately became friendly. He could, indeed, talk with the great without losing his

stature and converse with the lowly without embarrassment to them.

This story has been delightfully told by the Flexners. From the biography, a true picture of Welch emerges, skillfully depicted by expert hands. This is an outstanding biography of a great physician—a man not always easy to evaluate, but one whose influence in medicine will long be felt, since he was one of the greatest of four or five men who have served to make medicine in America what it is today.

MEDICAL EPONYM

POTT'S FRACTURE

This type of fracture was described by Percivall Pott (1713-1788), F.R.S., in *Some Few General Remarks on Fractures and Dislocations* (London: 1768). A portion of the text follows:

... when by leaping or jumping the fibula breaks in the weak part already mentioned, that is within two or three inches of its lower extremity . . . the inferior fractured end of the fibula falls inward toward the tibia, that extremity of the bone which forms the outer angle, is turned somewhat outward and upward, and the tibia having lost its proper support, and not being of itself capable of steadily preserving its true perpendicular bearing, is forced off from the astragalus [*sic*] inwards, by which means the weak bursal, or common ligament of the joint is violently stretched, if not torn, and the strong ones, which fasten the tibia to the astragalus and os calcis, are always lacerated, thus producing at the same time a perfect fracture and a partial dislocation, to which is sometimes added a wound in the integuments, made by the bone at the inner angle. . . .

COMMITTEE ON MATERNAL WELFARE

CASE HISTORY: FATAL ANAPHYLACTIC SHOCK RESULTING FROM PITUITARY EXTRACT

A forty-two-year-old primipara, whose past history was irrelevant, entered the hospital with pneumonia when about three months pregnant. The medical history states that she had had rheumatic fever and mitral stenosis, although the autopsy did not confirm the diagnosis. Eleven days after hospital entry, during her convalescence from pneumonia, the patient spontaneously miscarried; the placenta, however, did not come away. One ampule of pituitary extract was given for the purpose

of stimulating uterine contractions to aid in expulsion of the placenta; this was followed immediately by severe shock. There was no hemorrhage. At first, the patient appeared intensely red and felt weak and dizzy, and thirty minutes later, vomiting and sweating occurred, the lips became cyanotic, and she was pulseless. She remained in a state of collapse. A transfusion of 600 cc. of blood resulted in improvement for the next seventy-two hours, but death occurred at the end of this time, following delirium and a rapid rise in the pulse, respirations and temperature.

According to the death certificate, the cause of this fatality was "pulmonary embolism." Autopsy, however, revealed pulmonary congestion, retained placenta and recent thrombophlebitis of the right femoral vein but no evidence of a pulmonary embolus.

Comment. This is a very interesting case. Fortunately, an autopsy was performed. This death must have been due to circulatory shock following the administration of pituitary extract; no other conclusion can be drawn. As stated above, the placenta was still in the uterus at the time of death.

These are not the times in which to try to revolutionize medicine, but it does seem as if there should be some means whereby cases that are autopsied may have the true anatomic diagnosis recorded on the death certificate. Too often, the pathologist's diagnosis does not coincide with that of the physician, and so long as this obtains, our vital statistics will be inaccurate.

DEATH

HARRIS — A. E. HARRIS, M.D., of Lynn, died July 11. He was in his seventy-third year.

Born in Montville, Maine, Dr. Harris received his degree from Bowdoin Medical School in 1895. He was a former member of the staff of the Lynn Hospital and a member of the Massachusetts Medical Society and the American Medical Association.

His widow and a brother survive him.

MASSACHUSETTS MEDICAL SERVICE

FIRST CONTRACT INITIAL STEP IN COMPLETE SERVICE

The public is not yet willing to buy complete medical-service contracts, according to the studies made by the Massachusetts Medical Society of the medical plans in operation in other states. Therefore, the Massachusetts Medical Service is initiating its program with a partial-coverage contract, which includes hospital surgery, obstetrics and diagnostic x-ray service.

This first contract is the initial step in evolving a complete medical-care service. Present plans indicate that the second contract will cover all

hospitalized illnesses and that the third contract will cover hospital, office and home care so far as experience proves it advisable.

This gradual approach parallels the method used in developing the Blue Cross nonprofit plan for hospital care and is based on the necessity for educating the public gradually to the need for increasing expenditure to obtain more complete services. The Blue Cross contract was sold first to the individual subscriber on the basis of three cents per day; next, the subscriber was willing to spend more to protect both himself and his wife; and finally, the subscriber learned the value of buying a more expensive contract that would protect all members of his family under eighteen years of age.

OTHER STATES POINT THE WAY

The wisdom of a gradual development of the Massachusetts plan is borne out by the experience of medical-service plans in other states, where complete coverage has met with poor public response.

In Michigan, 187,000 surgical-obstetric contracts were sold as against only 5816 contracts providing complete medical coverage. In one year alone, Michigan lost \$75,000 on complete-coverage contracts, of which \$10,000 was lost on a single employee group. California has sold only 30,000 complete-coverage contracts in six years, and only 10,000 have been sold in New York.

PREMATURE CONTRACTS UNSATISFACTORY

The premature sale of complete-coverage contracts to a public uneducated to them brings disastrous results in many instances. In some states, compensation to family physicians dropped to from twenty to sixty cents on the dollar. In other states, the medical-service corporation went into debt to maintain payments to physicians.

Buffalo, California and Michigan are selling no more complete-coverage contracts, and all the states that began with complete-coverage contracts have been forced to revert to the issuance of the surgical-obstetric contract. "The surgical-benefit contract is more or less predictable from an actuarial basis," writes Philo Nelson, general manager of the California plan, "and is the soundest to begin with." John Mannix, executive director of the Michigan Hospital Service, who is closely affiliated with the Michigan Medical Service, states, "From the experience of Michigan, partial coverage is the only approach that is reasonable." The wisdom of the partial-coverage contract is further confirmed in a preliminary report made by the Superintendent of Insurance of the State of New York, who says: "A greater appeal seems to exist for surgical benefits only than for general medical coverage. This is due, perhaps, to the possibility of being con-

fronted with much more substantial bills for surgical services than for general medical expense. It is understood that the plans contemplate experimenting to a greater extent in this field."

By enthusiastically and actively supporting the program of the Massachusetts Medical Service, physicians of the State may help to avert the appearance, in Massachusetts, of a bill similar to the following, which will be supported next year by the New York Insurance Commission unless the medical profession of that state takes active steps:

"A hospital corporation may, by amendment of its charter, acquire the power to supplement its contracts for hospital service by provision for the furnishing of indemnity against physicians' fees for surgical and obstetrical care rendered" (Hampton Bill, New York Senate No. 1273 In. 1054).

WAR ACTIVITIES

OFFICE OF CIVILIAN DEFENSE

HOW TO PROTECT YOURSELF AGAINST GAS

Two recent operations letters dealt with the establishment of improvised decontamination stations and with the organization of decontamination services, respectively. This letter deals with personal protection against gas.

The following information on war gases is supplied by the United States Office of Civilian Defense for general publication because of the possibility that such gases may, at some time, be used by the enemy. If people will remember a few simple facts, they will have no unreasonable fear of this agent.

* * *

War gases stay close to the ground, for they are heavier than air. To get out of a gassed area, simply walk against the wind or go upstairs.

Gas is irritating and annoying to the eyes, nose, lungs and skin, but it is usually harmless if you do not become panicky but promptly leave the gas area and cleanse yourself. A soldier must put on a mask where it is necessary to remain in the contaminated area, but a civilian can go up on the second or third floor and literally ignore it, if the windows are kept closed.

If the gas should get on your skin, you can prevent it from doing much harm by sponging it off as quickly as possible with a piece of cloth, such as a handkerchief, and applying some neutralizing substance, followed by a thorough bath, preferably a shower, with common laundry soap and water.

If you are indoors, stay there with doors and windows closed, and go up to the second or third story. Stay out of basements. Turn off air-conditioning equipment, and stop up fireplaces and any other large openings.

Some gases are spread as oily droplets, which blister and burn the skin and eyes. If you are outside when gas is used do not look up. Tear off a piece of clothing or use a handkerchief to blot any drops of liquid from your skin and throw the contaminated cloth away. Blot; do not rub, as rubbing will spread the liquid. Then go home, if it is nearby, or to the nearest place where you can wash immediately with soap and water and cleanse yourself in the following manner:

(1) Remove all outer clothing outside the house, since

gas can be transmitted to others from contaminated clothing. Put it preferably in a covered garbage pail.

(2) Apply one of the following effective household remedies to the part of your skin that has been contaminated: Chlorox or a similar household bleach (for mustard gas); peroxide of hydrogen (for Lewisite); a paste or a 2 per cent solution of baking soda (one tablespoonful to a quart of water), if you have no bleach or peroxide. If you do not know the gas, use both bleach and peroxide. Keep the bleach and the peroxide out of the eyes. *Do not waste time looking for these remedies: bathe immediately if they are not at hand.*

(3) After entering the house, wash the bleach or peroxide from the hands with laundry soap and water and then wash the face. Remove the underclothing, place it in a covered garbage pail and enter the bathroom.

(4) Irrigate the eyes with large amounts of a lukewarm 2 per cent solution of baking soda (one tablespoonful to a quart of water), or else with plain water. Use an ordinary douche bag or an eye irrigator. If you do not have these, let plain warm water pour into the eyes from the shower, washing them thoroughly. Do not press or rub the eyes.

(5) Lastly, take a shower, using laundry soap and hot water.

(6) If the nose and throat feel irritated, wash them out with the baking soda solution.

(7) If the chest feels heavy and oppressed, if you have any trouble breathing or if cigarette smoke becomes distasteful, lie down and stay perfectly still until a physician sees you.

(8) If blisters develop, be careful not to break them and call a physician.

Remember:

Soldiers require gas masks because they must remain in the contaminated area. Civilians can get out of the gassed area or get above the level of the gas, where they do not need gas masks or protective clothing.

Injured persons who are gassed require decontamination before they can be admitted to hospitals. All other civilians can best prevent any serious injury by promptly helping themselves in the manner outlined, using a kitchen or bathroom, laundry soap and water, and a few materials found in every household.

CORRESPONDENCE

NAVAL MEDICAL OFFICER PROCUREMENT

To the Editor: The imminent conscription of all medical skills for the war effort has been amply outlined and urgently stressed in your columns, especially in the issue of July 2. There has been a tendency among physicians to interpret this need and opportunity as one of service in the Army. Indeed, rumors have come to my attention that doctors were no longer needed in the Navy and that commissions in the Naval Reserve were not being granted or, if granted, the call to active duty was likely to be deferred.

All of us recognize the larger numerical need of the Army, but the proportional need of the Navy remains just as great. Current directives inform us that quotas of medical officers of the Naval Reserve have been greatly extended and that many more applications for commis-

sions should be obtained as promptly as possible. Further more, physicians commissioned in the Naval Reserve may ordinarily anticipate prompt call to active duty.

The Office of Naval Officer Procurement is located on the sixth floor of the North Station Office Building, 150 Causeway Street, Boston. Captain C H J Keppler is in charge, and the office is open daily from 8 00 a m to 4 30 p m to receive applications or to supply information. If seriously interested local medical societies, hospital staffs or other medical groups at a distance from Boston desire a representative of the Naval Reserve Medical Corps as a speaker, every effort will be made to accommodate them.

LIEUT COMDR ROBERT S PALMER, MC V(S), USNR
Office of Naval Officer Procurement

REFUGEE PHYSICIANS'

To the Editor We, the undersigned as physicians who have come here from foreign countries in recent years take note of the letter from Dr P C Zanfagna, president of the Greater Lawrence Medical Association, published in the June 18 issue of the *Journal*.

The whole tenor of this letter is reminiscent of familiar propaganda attacking groups that are weakest from an economic and legal point of view, groups to which we as immigrant physicians, belong.

Dr Zanfagna refers to Massachusetts as a 'dumping ground for physicians not wanted elsewhere'. In the course of recent immigration, approximately 200 immigrant physicians obtained licenses in Massachusetts. Not more however, than 100 are in general practice, and they represent 126 per cent out of the total number (7889) of registered physicians. In 1942, immigration stopped.

The Board of Registration in Massachusetts is accused in this letter of licensing aliens whose class of school and educational background cannot be verified. This is not true, since practically all these immigrant physicians graduated before 1933, when the status of their schools was known and had been verified by the American Medical Association and National Board of Medical Examiners. The same scientific and ethical qualifications were demanded of them when they took their state board examinations in Massachusetts as are required of native physicians. When it is realized that the great majority of these physicians, who are between forty and sixty years of age, successfully passed the examinations despite the mental disaster they had experienced and the language hurdle they had to overcome, the allegation that they are ignorant and incompetent is nothing less than absurd. Most of these men had been in practice for fifteen to twenty years before they came to this country. The implication that spies or saboteurs can be guarded against by requiring citizenship is a condition of licensure strikes us as bordering on the preposterous.

The immigrant physician is not a little confused by the fact that while the shortage of physicians mounts steadily, he willing to serve in any capacity and not wanting to impose on native physicians or compete with them, stands waiting. Let him be taken into the Indian Service or into a medically unmanned area in any state. He will go gladly if given the opportunity.

We agree that immigrant physicians should do military service along with native physicians, to state, however, that Major Seeley does not want these men to treat our boys is untrue. A number of the undersigned and others went to the Army Base on the very first day of

the war to offer their services in any capacity, they were informed that the law prohibits the commissioning of non citizen physicians. Practically all immigrant physicians responded to the request of the Procurement and Assignment Service and offered their services. The undersigned physicians, speaking on behalf of the majority of immigrant physicians in Massachusetts, take this opportunity to appeal to the Massachusetts Medical Society and the American Medical Association for help in becoming acceptable for military service, and whenever and wherever they may be needed. This is the least they can do to show their gratitude to this country, which gave them a haven of refuge and a new home.

Perhaps, those whose ancestors came to these shores as aliens should look back to those times and compare for themselves the former hospitality with what is extended to us by some of them today.

REPORTS OF MEETINGS

MASSACHUSETTS TUBERCULOSIS LEAGUE

On April 9, the Diabetes Committee of the Massachusetts Tuberculosis League met at the Myles Standish Hotel Boston. Under the leadership of Dr Elliott P Joslin, this committee has worked steadily against diabetes since its founding in March 1935. The committee is very small, and its annually invited representatives are among those persons most interested in diabetes in the eleven largest hospitals of Boston.

Since the majority of deaths from diabetes occur in these hospitals, it was believed that the physicians concerned should be the ones to study most intensively prevention and treatment seeking to correct their own mistakes than to initiate, as was done in some other cities, a popular organization to combat diabetes. Various procedures have been developed in combating diabetes as a result of repeated interchange of experiences on every phase of the treatment in the hospitals of Boston. Successive yearly meetings have recorded improved results.

Through the years, the physicians representing the hospitals have attempted to meet and discuss diabetes with physicians whose cases sent to the hospital have proved serious or obscure.

To the members of this committee come interesting bits of literature on diabetes. At the meeting was presented Volume I of the *Proceedings of the American Diabetes Association*, the first annual meeting having been held at Cleveland on June 1, 1941. Also presented was the first copy of *Diabetes Abstracts* issued in January, 1942 a quarterly of the new American Diabetes Association. These abstracts, said by the physicians to cover the field splendidly, are produced at the expense of the Eli Lilly Research Laboratories, which were already equipped to gather this material.

The Diabetes Committee consists of Dr Elliott P Joslin chairman, Dr Herbert Lombard, Dr Alton S Pope, Dr Francis P Denny, Dr Charles F Wilinsky, Arthur J Strawson, secretary, and Dr Henry D Chadwick, ex officio.

PLYMOUTH DISTRICT MEDICAL SOCIETY

The annual meeting of the Plymouth District Medical Society was held at the Bridgewater State Farm on April 16, 1942. The minutes of the previous meeting were read by Dr. R. C. McLeod.

Dr. R. A. Kruger reported small progress in the investigation of the group health insurance for the members of the society. At least one company would require 50 per cent of the membership to join. All policies would be on an annual basis and cancellable at the discretion of the company at the end of one year. It was Dr. Kruger's opinion that none of the companies were really anxious for this type of business. It was voted to poll the entire membership as to its wish to investigate the matter further. Dr. J. J. McNamara offered to present an insurance man at a later meeting to explain further.

The officers for the ensuing year were elected as follows: president—C. D. McCann; vice-president—E. L. Perry; secretary—R. C. McLeod; treasurer—A. L. Hurlburt; councilors—W. H. Pulsifer (nominating), P. H. Leavitt (alternate, nominating), J. E. Brady, W. T. Hanson, Charles Hammond, P. B. Kelly, G. A. Moore and D. W. Pope; censors—W. T. Hanson (supervising), J. H. Dunn, G. A. Buckley, H. F. Pierce and A. W. Carr; orator—W. C. Gould; librarian—J. H. Weller; and commissioner of trials—J. A. Carriuolo.

Dr. G. A. Moore, the retiring president, thanked the faithful members for their attendance and help throughout the year, and presented small tokens to the members present. Dr. P. H. Leavitt gave a report on progress in the Society's medical-insurance program. Dr. Moore presented Dr. F. E. Wheatley as orator. Dr. Wheatley also was orator twenty-five years ago and remarked that following both appointments a world war had occurred.

Dr. Wheatley's paper concerned roentgen-ray therapy. As early as 1904 in Boston, Dr. Francis Williams wrote a book on x-ray treatment, but early doses were uncontrollable. In 1914, the Coolidge tube, which allowed dosage regulation, was introduced. It was found that high-voltage machines give off as many nonpenetrating rays as low-voltage ones, and require screening with aluminum or other metals. In the early 1920's, potentials as high as 200 kilovolts were available. Huge doses under high voltage were thought lethal to new growths, but soon proved lethal to healthy tissues also. Repeated divided doses afford a better chance for the normal tissues to recover. Radiation for deep therapy is still in a chaotic state, since high-voltage treatment has been a disappointment. In inflammatory processes of acute nature, many small x-ray doses do very well. Precancerous lesions are best treated by small doses. A slowly growing lesion often requires heavier total dosage than the rapidly growing type. Advanced and hopeless cases of deep cancer can only be damaged, and such sequelae as burns and x-ray sickness may be worse than the disease itself, and may help to kill the patient sooner. The pros and cons of x-ray exposure before or after breast amputation are still under discussion. Some believe that perhaps 10 per cent more patients live five years after having x-ray treatment. In other constitutional conditions, such as leukemia, Hodgkin's disease and splenomegaly, rapid and massive dosage is a poor choice. Weaker doses have accomplished much more, and no fatalities have resulted for two or three years after treatment. The previous conception of x-ray therapy has been correlative to the idea of a cure of malignant tumors. In the speaker's opinion, more attention should be given to the palliative effects.

BOOK REVIEWS

Shock Treatment in Psychiatry: A manual. By Lucie Jessner, M.D., Ph.D., and V. Gerard Ryan, M.D. With an introduction by Harry C. Solomon, M.D. 8°, cloth, 149 pp. New York: Grune and Stratton, Incorporated, 1941. \$3.50.

A new kind of treatment for psychiatric disorders has been developed since 1928, when Sakel first began giving insulin in doses sufficient to produce hypoglycemic states. Insulin therapy was subsequently augmented, although not entirely replaced, by the Metrazol convulsive treatment of von Meduna, in 1933. The third method,—electric convulsive therapy,—introduced by Cerletti and Bini in 1937, is now extensively used, and in many clinics has displaced the more dangerous, less well-controlled shock treatment by insulin or Metrazol.

This small but excellent book covers the historical data, the details of the use of the three methods and their dangers, the selection of patients, the theoretical considerations and the effect of shock treatment on the course of various mental diseases. The manual is timely, accurate, sufficiently detailed and soundly written. There is a voluminous but selected bibliography. The price charged for a book of less than one hundred and fifty pages is quite high.

Body Mechanics in Health and Disease. By Joel E. Goldthwait, M.D., LL.D., Lloyd T. Brown, M.D., Loring T. Swaim, M.D., and John G. Kuhns, M.D. With a chapter, "The Heart and Circulation as Related to Body Mechanics," by William J. Kerr, M.D. Third edition, completely revised and reset. 8°, cloth, 316 pp., with 121 illustrations. Philadelphia: J. B. Lippincott Company, 1941. \$5.00.

The main theme of this work is the effect of poor body mechanics on the various systems of the body. It is easy for one to appreciate the influence of improper posture on the joints and their supporting structures. Just as important, but far less obvious, are the secondary effects on digestion, circulation and respiration. The authors discuss the diagnostic features of poor body mechanics and outline the proper treatment for the various types.

This book deals largely with end results and, by emphasizing the evils, points the way to prophylactic care in early life, when habits are formed. A good bibliography is appended for more detailed study of the particular problems.

Edith Cavell. By Helen Judson. 8°, cloth, 288 pp. New York: The Macmillan Company, 1941. \$2.50.

Edith Cavell's tragic story has often been told, but nowhere better than in this work by an author who has made a profound study of Miss Cavell's whole career. The book is well written and brings out clearly Miss Cavell's character, the type of work that she was engaged in as a nurse, the reasons for her being apprehended by the Germans and the details of her execution. Although much of this material has been known for years, Miss Judson has added new details of historical importance. The author, moreover, has been careful not to emphasize the emotional effect of Miss Cavell's death; she has written a straightforward account such as, one presumes, Miss Cavell would have approved herself. There is no hatred or bitterness in the book, and the standard followed is similar to that set by Miss Cavell in her famous remark: "I know that patriotism is not enough; I must have no hatred and no bitterness toward anyone."

THE PROBLEM OF CERTAIN TROPICAL DISEASES IN THE WAR*

HENRY E. MELENEY, M.D.†

NEW YORK CITY

TROPICAL medicine has not been one of the major specialties of American medicine, although it has been a field in which some of the most notable achievements have been made by American physicians. A few universities, especially Harvard and Tulane, have had departments of tropical medicine, but the greatest activity in this field has been carried on by the United States Army, Navy and Public Health Service and the Rockefeller Foundation. The interest of most medical schools and practitioners has been absorbed by their local problems, which have been quite different from those of the tropics. Now we are faced with the necessity of sending large numbers of troops to countries where tropical diseases are the chief hazards, and medical officers, whose duty it is to keep the troops in fighting condition, are confronted with the problem of diagnosing, treating and preventing diseases that have not been a part of their training and experience. Those of us who remain in civilian practice may also be faced with similar problems when the troops return to civil life. It is therefore appropriate to call attention to some of the problems in tropical medicine that our present national effort involves.

MALARIA

The most important of these problems is malaria, which, clinically, really comprises three separate diseases—the benign tertian and quartan types, which cause great disability but few deaths, and the malignant, tropical, estivoautumnal type, which may simulate a wide variety of other diseases, is often fatal and is frequently associated with severe complications, such as blackwater fever and profound anemia. Diagnosis is sometimes difficult because of the bizarre manifestations of this dis-

ease, and also because the parasitized red blood cells stick to the walls of capillaries during the second twenty-four hours of the asexual life cycle and may not be found in the circulating blood. The important thing is for the physician to have malaria constantly in mind in every case of illness in the tropics, and to make repeated blood examinations on consecutive days until malaria is diagnosed or definitely excluded.

The treatment of malaria is not the simple procedure that it is often thought to be. Even after a supposedly complete course of treatment with quinine or Atabrine, relapses occur in about 50 per cent of cases of tertian and quartan malaria, and in about 20 per cent of cases of estivoautumnal malaria; and in estivoautumnal malaria, the early relapse may be fully as severe as the first attack. We do not yet know whether relapses are due to the continuation of the asexual cycle in tissues outside the general circulation, such as the splenic pulp, where the parasites are protected from a sufficient concentration of the drug to kill them, or whether they are due to a so-called "exoerythrocytic form" of the parasite that multiplies in the reticuloendothelial cells of the body. The tendency in the last few years is to use short, vigorous courses of treatment for the acute attack and to treat the relapses as they occur; but many authorities still believe that the treatment should be continued for eight to ten weeks, a procedure that is very difficult to carry out in troops on active service.

The prevention of malaria in troops by the prophylactic use of quinine or Atabrine is unsatisfactory for several reasons. It requires an enormous amount of these drugs, which are now difficult to obtain. It requires responsible persons to administer the drugs to troops individually, to be sure they are taken. The drugs cause aviators to perform abnormally at high altitudes. Finally, these drugs are not true prophylactics, since they have no lethal effect on the sporozoite introduced by

*Presented at the annual meeting of the Massachusetts Medical Society, May 26, 1942.

†Professor of preventive medicine, College of Medicine, New York University.

the mosquito, and only postpone the clinical disease in infected persons until the drug is no longer administered.

The prevention of malaria by the control of mosquitoes in the tropics is also a tremendous problem. Even in fixed military establishments, it requires expert organization, constant vigilance and great expense. When troops are operating in the field in endemic areas, it is impossible to protect them from infection. Bed nets are poor substitutes for adequate screening, and mosquito repellents have not been developed to a point where they will protect persons from mosquito bites longer than forty-five minutes under sweating conditions.

Even in our fixed bases in the Caribbean, the control of *Anopheles* breeding may be a serious problem. In one area, for instance, an important malaria vector breeds in the leaves of a plant growing high in the trees. Another problem is the transportation of dangerous species of *Anopheles* by airplanes and fast ships across the ocean. In 1930, *Anopheles gambiae*, the chief vector of malaria in West Africa, was discovered on the northeastern coast of Brazil and soon caused a devastating epidemic in its new habitat. By strenuous and costly efforts, the Brazilian government and the Rockefeller Foundation apparently eradicated the mosquito from the area in 1940, but the threat of its reintroduction is again indicated by the recent finding of this mosquito on three occasions in airplanes reaching Brazil from Africa.

Troops and civilians returning from the tropics to nonendemic areas of malaria in the temperate zones will undoubtedly bring with them latent and chronic malarial infections, which the medical profession must be on the alert to diagnose and treat to avoid the establishment of the disease in the civilian population. This happened in England after World War I, and may occur even in New England after the present war.

ENTERIC DISEASES

Typhoid fever was well controlled by vaccination and sanitation in American forces during World War I, but it was not entirely eliminated, especially in France, where troops operated in unprotected areas. During the present war, with troop movements much more rapid and with large numbers of them operating in the tropics, we must expect a higher incidence of typhoid fever unless emergency sanitation is more efficient than in the last war, and unless the troops are educated to protect themselves from polluted water and food under the most trying circumstances.

The dysenteries and diarrheas were formerly the most prevalent and disabling diseases among troops in camp and on the march. In World

War I, although these diseases had dropped to seventh place among the causes of illness in the American army, bacillary dysentery was an important cause of illness during the active summer campaigns in France. In the Philippines, even though there was no fighting, the diarrheal diseases caused by far the highest admission and death rates among our troops. There is at present no specific preventive against either bacillary or amebic dysentery, and although we now have effective drugs for the treatment of both conditions, some cases, especially those of amebic infection, are likely to be insufficiently treated under war conditions and may lead to chronic disability or become sources of infection among the civilian population after the war. Drug prophylaxis of both bacillary and amebic dysentery has been suggested, but the expense and labor entailed in such a procedure make it impractical except in the presence of an epidemic, and in such a situation, sufficient quantities of the drugs would probably not be available. Here again, prevention must depend solely on the most rigid sanitation and education of the troops.

The mild epidemic diarrheas must not be forgotten, since they may disable essential units during crucial periods. We now recognize *Salmonella* diarrhea, *staphylococcus-toxin* diarrhea and water-pollution diarrhea as frequent epidemic diseases among the civilian population. Although they may occur in any latitude or in any season, they are more frequent during warm weather. The greatest care in the handling and preparation of meats, salads, milk and pastries must be observed to prevent food-borne epidemics. One such epidemic was reported among troops who ate insufficiently cooked bread during World War I. Water-pollution diarrhea is perhaps likelier to occur as scattered cases in soldiers drinking from polluted sources than as an epidemic, but its possibility must be kept in mind wherever public water supplies are used, and the danger of a typhoid epidemic, following it after the usual incubation period, must always be remembered.

It may seem farfetched to mention cholera as a possible problem in our war effort. But it must be remembered that the disease is endemic in India and Central China, that there was an epidemic of it in the Philippines as late as 1934, and in the coastal regions of China in 1938, and that it is a constant threat in the Malay Peninsula and Burma. It is reported to be prevalent at the present time in Greece, and might spread easily to the Balkans, Russia and other near-by countries. Although a vaccine against it is available for the use of our military forces, protection is only partial and of short duration, and requires repetition in the endemic areas every six months.

With the destruction of cities and the migration of refugees, it will be surprising if severe epidemics do not occur, and the possible operation of our troops in devastated areas may expose them to the disease.

MISCELLANEOUS DISEASES

Epidemic louse-borne typhus fever is, of course, one of the greatest threats to armies, prison camps and starving populations in the cooler climates, but it has also been epidemic in Spain during the past two years and is almost constantly present in North Africa and China. Within the last few years, murine typhus in rats has been found to be an endemic disease in most parts of the world, being transmitted to man by the rat flea. There is only a questionable difference between the murine and the epidemic louse-borne strains of the typhus rickettsia, and evidence has been brought forward, especially from China, that the murine disease in man can give rise to louse-borne epidemics. The delousing of troops was a major activity of the medical department of the American army in France during World War I, and the maintenance of a louse-free army during the present war will require constant alertness and efficient delousing facilities. Although a vaccine against typhus has been developed, its protective power is questionable, and the results of further experimentation and of trial in large groups of exposed persons must be awaited before any statement can be made concerning its value.

Relapsing fever must not be forgotten as a louse-borne disease, which either accompanies typhus fever or appears as an independent epidemic. The tick-borne variety of the disease is widely distributed in Africa and Central and South America, and even occurs in the western United States. It must be kept in mind among troops operating in these areas.

The war in the Orient has centered about areas where bubonic plague is most prevalent. Java, Malaya, India and Central and South China have found the disease a serious problem during the present century. There are indications of its increase to epidemic proportions in certain parts of China at the present time, and with the destruction of cities and consequent migration of rats, it will not be surprising if the disease gets out of control over wide areas. Wherever there are bubonic cases, a certain number of pneumonic cases occur, and under conditions of crowding, both of troops and civilian populations, the threat of pneumonic epidemics may be present. Even in our own country, the so-called "sylvatic plague" in ground squirrels and other wild rodents has advanced from the Pacific Coast across the continental divide and is now moving

slowly toward the central states. Although this will probably not be a military problem, it is a serious problem to the United States Public Health Service, whose functions are now put under stress by the war effort. Recent discovery that the sulfonamide drugs are of value in the treatment of bubonic plague is hopeful in view of the high case fatality rate of the disease. In prevention, vaccine is thus far only partly protective but is being held in readiness for troops likely to be exposed. Rat control is one of the most difficult procedures, even under the most favorable circumstances, and will hardly receive attention in any except the most seriously affected plague areas in the Orient while the present struggle lasts.

The campaign against yellow fever has fortunately eliminated epidemics of this disease in the Western Hemisphere, but the discovery of its endemic existence in the jungles of South America makes constant vigilance necessary to prevent it from extending to cities where the *Aedes aegypti* mosquito can start epidemics. In Africa, it is still epidemic as well as endemic, and its presence in the Egyptian Sudan leads to the possibility that it might be transported in infected mosquitoes to India. In the past, lack of rapid transportation from Africa has probably been the only reason why the disease has never occurred in Asia. If such a spread should now occur, the result might be one of the greatest calamities of the war. The most careful inspection and fumigation of all airplanes before leaving endemic areas and after arriving at their destinations constitute the only method by which Asia can be protected from this invasion. Vaccination against yellow fever apparently affords complete and permanent protection, and must be performed on all persons going to or through endemic areas.

Dengue fever, which may be considered a mild relative of yellow fever, is caused by a filterable virus having the same incubation and infectious periods in mosquito and man, is transmitted chiefly by *A. aegypti* and exists in nearly all parts of the tropics. It may cause disabling epidemics among troops at crucial periods. Unfortunately, one attack produces only temporary immunity so that subsequent exposure may again lead to further epidemics in the same group.

A number of other diseases should be mentioned to complete the picture of the hazards to which our troops may be exposed in the tropics. Although none of these will occur in epidemic proportions or even in high incidence, they may present diagnostic problems to medical officers or, after the war, to civilian practitioners.

Leprosy, yaws, leishmaniasis in its visceral form, kala-azar, or in its Oriental or American cutaneous

form, African trypanosomiasis, schistosomiasis, the blood-fluke disease, filariasis and hookworm are major diseases in some parts of the tropics and must be constantly kept in mind.

Mention should also be made of the effects of tropical heat on the white man. In addition to the acute conditions of sunstroke and heat stroke, and the salt loss from excessive perspiration, there are more insidious conditions that often produce disability and are not well understood. Dietary demands are different from those in the temperate zones, with a tendency to a higher relative intake of carbohydrates, which may predispose to intestinal infections. This may also be related to a greater demand on the part of the body for certain vitamins, particularly those of the vitamin B complex. In this connection, there is some evidence that thiamine requirements are higher in the tropics. Sprue is undoubtedly a deficiency disease in some way related to this field.

There is also evidence that the endocrine glands, particularly the adrenal glands, may not function normally in the tropics, as manifested by asthenia and low blood pressure. All these disturbances may contribute to the exhaustion that so often drives the white man home from the tropics, or makes him lose the energy necessary to fight a vigorous campaign there.

This brief summary of some of the medical hazards of the tropics indicates clearly that the medical officers of our armed forces should be much better prepared for service in these areas than most of them are. The Army and Navy are giving short courses in tropical and parasitic diseases to a limited number of the medical officers going to the tropics, and two medical schools have given voluntary courses to officers awaiting orders. This, however, is an emergency procedure and cannot possibly provide such knowledge to all the medical officers who should have it. Our lack of interest in the tropics and the scarcity of tropical diseases in this country have led to the almost total neglect of instruction in tropical medicine and parasitology in most of the medical schools of the country. It is not too late, however, to remedy this situation for the benefit of our present medical students, who may see service in the tropics before the war is over. Already such instruction is being organized in certain medical schools, and it should be in all of them. After the war, our interest in the tropics and the possibility of the occurrence of more tropical diseases in this country, because of returned troops and greater travel, should lead to permanent provision for adequate undergraduate and postgraduate instruction in this vital field of medicine.

THE PRESENT PROGRAM FOR THE IMMUNIZATION OF MILITARY PERSONNEL*

JOHN F. ENDERS, PH.D.†

BOSTON

RECENT advances in our knowledge of pathogenic bacteria as antigens and in the nature and immunologic properties of viruses have led to the development of a number of new procedures for the production of active immunity.

The adoption of these and the retention of the tried and true vaccinations against smallpox and typhoid fever by the United States Army and Navy, although usually making the first week or so of the recruit's service a far less agreeable period than it was heretofore, will undoubtedly help to preserve his life and maintain him in fighting trim on those fronts, ranging from the Arctic to the tropics, where he seems destined to fight.

My purpose is to review briefly such procedures as are now in routine use in both major arms of

our forces and to comment on certain improvements that might be made in some of them according to investigations now in progress.

* * *

Smallpox

There is little to be said concerning vaccination against smallpox that is not familiar to everyone. In both services, it is required for all personnel and is effected immediately on induction and every three years thereafter in the Army and every four years in the Navy. Under special circumstances, such as departure for an active theater of operation, vaccination must be carried out unless it has been done within the preceding twelve-month period. During the last few years, vaccine virus propagated in tissue cultures or in the developing hen's egg has been suggested as a substitute for calf lymph. Such preparations, however, have not proved satisfactory, and the traditional material is employed

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1942.

†Assistant professor of bacteriology and immunology, Harvard Medical School.

exclusively among the armed forces as in civilian life.

Stress is laid on the use of the proper technic for introducing the virus into the uppermost layer of cells in the dermis. The medical officer also must be thoroughly familiar with the three types of reaction that may occur—immune, accelerated and primary. If no reaction or a doubtful reaction is obtained, vaccination must be repeated several times with virus of high potency to ensure that a genuine immunity exists.

Typhoid and Paratyphoid Fevers

Antityphoid vaccination is, of course, also mandatory in both services. The important observations of Grinnell,¹ published in 1932, on dissociative changes in the direction of loss of virulence and altered antigenicity that had taken place in the Rawlings strain of *Eberthella typhosa*, then almost universally employed as the source of typhoid vaccine, have led to the substitution of the highly virulent and potent antigenic P-48 strain by the Army officials. This change should definitely improve the efficacy of the vaccine.

For a time *Salmonella paratyphi* and *S. schottmülleri* (paratyphoid A and B bacilli) were omitted, but at present they are again represented in the vaccine, which contains 1,000,000,000 typhoid organisms and 250,000,000 each of the paratyphoid bacilli per cubic centimeter.

The vaccine is given in the usual three doses of 0.5, 1.0 and 1.0 cc. at weekly intervals, and the injections are attended by the local and generalized reactions of varying severity unpleasantly well known to most of us. It is possible that such variation in reaction may, in part, be attributed to the mode of administration, and it has been suggested that care should be taken to introduce the material quite superficially under the skin, first making certain that the needle has not entered a small blood vessel.

It has been found by Siler and his colleagues² at the Army Medical School that a recall, stimulating or so-called "booster" dose of the vaccine given in the amount of 0.1 cc. intradermally one year after the initial series of injections effectively restores the antibody level, and so presumably efficiently maintains resistance. On the basis of these observations, the Navy has adopted as routine the administration of an intradermal recall injection every year, although, so far as I am aware, the Army still holds to the older procedure of re-vaccinating every three years, with the exception, as in smallpox vaccination, of those persons leaving continental United States for an active theater of operations.

Since intradermal inoculation of the vaccine is usually attended by reactions of less intensity compared to subcutaneous injection, and since the antibody response is excellent, this method should come into general use in the near future.

Under present circumstances, the desirability of including the paratyphoid bacilli and possibly even other varieties in the vaccine leads to the practical certainty of severe reactions due to the presence of large quantities of unessential bacterial proteins and other constituents. The isolation of a complex carbohydrate-lipid-peptide antigen by Boivin et al.³ in France and Raistrick and Topley⁴ in England from various species of the typhoid-paratyphoid group suggested a possible method of vaccination in which the injection of a large proportion of presumably unnecessary bacterial substances might be avoided. Morgan,⁵⁻⁷ in our laboratory, has produced from the typhoid bacillus grown on a medium of known constitution an antigen similar to those described by the French and English workers. Although definitely toxic, this substance has been found to stimulate effectively the production of mouse-protective antibodies when injected in extremely small amounts into human volunteers. Thus, a comparison of the antibody levels following injection of this purified antigen with those obtained after the usual series of injections with typhoid vaccine indicates that they are about equally effective. Of particular significance is the fact that, in the quantities employed, the purified antigen gave definitely milder reactions, characterized merely by local manifestations. Obviously, much further experimentation is necessary before one should contemplate substituting chemical derivatives of this sort for the whole bacillus, but the observations I have outlined encourage such research.

Tetanus

Concerning the very important problem of the prevention of tetanus, all the evidence at hand indicates that we are in a much more satisfactory position than we were during the last war, when antitoxin was the only available prophylactic. In addition to the disadvantage of using a foreign protein,—which is so liable to induce hypersensitivity,—the brevity of the period of its effectiveness following injection represents a distinctly undesirable feature. Ramon's discovery that tetanus toxin treated with 0.3 per cent formalin and maintained at 37°C. for several weeks resulted in a product exhibiting no toxicity but strong antigenicity has given us a method of safely and conveniently inducing a basic active immunity of long duration that may be quickly enhanced, when desired, by a single stimulating dose of the toxoid.

All military personnel on induction are now immunized either, as in the Army, by three injections of the plain or liquid toxoid or, as in the Navy and Marine Corps, by two injections of alum-precipitated toxoid.

The liquid toxoid is administered subcutaneously in quantities of 1 cc. at intervals of three or four weeks, and a single stimulating dose of 1 cc. is given under normal conditions twelve months after the last of the three initial injections. In wartime, a recall dose is injected during the month prior to departure for a theater of operations, unless such departure is within a period of six months subsequent to the stimulating dose or within six months subsequent to the initial series.

An emergency dose of 1 cc. of toxoid is given to soldiers wounded or burned on the battlefield, to patients undergoing secondary operations or manipulations of old wounds, when deemed advisable, and to others incurring nonbattle wounds likely to be contaminated with *Clostridium tetani*. This emergency dose in vaccinated persons appears to replace effectively the use of antitoxin.

In the Army, a record of tetanus immunization, if properly completed, is stamped on the identification tag. To wounded men who have not received all the injections or whose vaccination record is not available, tetanus antitoxin is administered at the same time vaccination with toxoid is begun.

Although parenteral injection of toxoid is far less likely to cause anaphylactic reactions than that of antitoxin, these have occurred on the administration of toxoid to persons allergic to various materials and occasionally to those who have previously received toxoid. Accordingly, in the Army, the following precautions must be observed in carrying out the vaccination: adrenalin should always be on hand, and intradermal sensitivity tests, 0.1 cc. of a 1:100 dilution of toxoid being used, should be done on all who have a history of previous allergic manifestations, who have exhibited untoward reactions to a previous dose of toxoid and who have received toxoid in the initial immunization series after an interval longer than four weeks. When mild reactions occur in the initial series, immunization can be completed by the administration of not more than 0.1 cc. of toxoid in three or four doses at daily intervals.

To my mind, these precautions are very well worth observing, not only by the medical officer but by anyone who undertakes to administer toxoid. It should, however, be clearly understood that the percentage incidence of such reactions has in the Army been extremely low and that they have in no way interfered with the tetanus-immunization program. Most of them seem to

have been due to certain brands of peptone employed in the mediums for growing the tetanus bacillus. In the bacteriological laboratory at the Harvard Medical School, a medium has been developed by Mueller⁸ that does not include peptone and that promises to permit the production of a toxoid that should give definitely fewer reactions.

In the Navy and Marine Corps, alum-precipitated toxoid is given in two injections of 0.5 cc. each by the intramuscular route, with an interval of not less than four and not more than eight weeks. In addition, a stimulating dose of 0.5 cc. is given once a year and repeated, if possible, before the zone of combat is entered. The emergency dose of toxoid is likewise 0.5 cc. As in the Army, to persons not satisfactorily immunized with toxoid, antitoxin is given in case of necessity, at which time active immunization with the toxoid is inaugurated.

The adoption of different preparations of tetanus toxoid by the two divisions of our forces reflects the diversity of opinion that prevails among immunologists concerning the relative merits of the plain or liquid and alum-precipitated toxoids. Certain persons in the Army prefer the former in the belief that its sensitizing properties are less than those of the alum-precipitated material and that it causes fewer reactions. There is no conclusive evidence that this is so, and certainly the convenience of administering only two doses of the precipitated toxoid is a definite advantage.

Yellow Fever

For a time, vaccination against yellow fever was required for all personnel in both the Army and Navy. Now, however, the Army has restricted its use to those about to depart for areas in which the disease is endemic. The vaccine developed by Theiler and Smith⁹ of the International Health Board at the Rockefeller Foundation consists of the living virus of yellow fever attenuated in virulence by prolonged passage in chick-embryo tissue cultures. At present, such a virus, propagated in the developing hen's egg, is employed for vaccination. One dose of 0.5 cc. of the concentrated virus-containing material, diluted 1:10 with sterile physiologic solution, is injected subcutaneously. Immunity results within a period of seven to ten days and lasts for at least three or four years and probably much longer. In perhaps 5 per cent of those inoculated, mild febrile reactions may be expected from the fifth to the seventh day following vaccination. Yellow-fever vaccine should not be given at the same time as smallpox vaccine, and an interval of at least five days must elapse before the latter is applied. There is no contraindication,

however, to simultaneous vaccination against yellow fever, tetanus and the enteric diseases.

Since the attenuated virus is extremely labile and readily becomes inactivated at ordinary temperatures, great care must always be taken to keep the vaccine at a temperature not higher than 4°C. Any diluted vaccine that has stood longer than three hours at room temperature must be discarded.

The vaccine in recent years has been administered without serious consequences to over 2,000,000 persons in South America and elsewhere under the supervision of the Rockefeller Foundation.

Cholera and Plague

In special instances, cholera and plague vaccines are used. Troops or naval forces about to enter areas where cholera is endemic or epidemic or where there is a serious threat of exposure to bubonic plague are given the appropriate vaccine. The cholera vaccine consists of 8,000,000,000 killed vibrios per cubic centimeter. The organisms are derived from a recently isolated strain, which should tend to ensure good immunizing properties. The suspension is injected subcutaneously in doses of 0.5 and 1 cc at an interval of seven to ten days. In contrast, the plague vaccine available, at least until recently, is made from old stock strains, and accordingly, its antigenic potency is open to considerable question. Until we have a better preparation, this material, which contains 2,000,000,000 organisms per cubic centimeter, is being employed and is administered in the same manner as the cholera vaccine. Up to the middle of last February, the Army had received no reports of untoward reactions following the injection of either preparation.

Everyone is aware that the efficacy of these vaccines is still in doubt. Although the experience of the British and East Indians with cholera vaccination and that of the Plague Commission with prophylaxis against plague in India strongly suggest that such procedures tend to decrease the incidence of both diseases, as well as to lower the mortality, it is as yet impossible to place as much confidence in them as we do in smallpox vaccination and the others that I have mentioned. Research by certain groups in this country with the object of obtaining better products is being actively pursued.

Typhus

Some allusion, perhaps, to vaccination against typhus fever of the classic or European variety is

appropriate. The prospect of the entrance of our forces into regions where this disease is endemic or epidemic makes vaccination highly desirable. A suitable preparation was believed to be at hand in the Cox¹⁰ yolk-sac vaccine. This, indeed, was used for a time in the Army and Navy. Tests, however, of its effectiveness as an antibody stimulant were disappointing, and its use has been discontinued. Vaccines prepared by different techniques, however, are available and are under investigation. Of these I shall mention only one, since I have firsthand knowledge of it.

This vaccine, devised in the bacteriological laboratory at the Harvard Medical School, consists of a suspension of killed rickettsias of the European type. The organisms are obtained from mice whose resistance to infection has been reduced by preliminary heavy exposure to x-rays. Experiments with guinea pigs and cotton rats have indicated that the material induces satisfactory immunity. Moreover, the serums of a small group of human beings, drawn from two to six weeks after a series of injections, have been shown to contain considerable amounts of antibody, which is capable of protecting both guinea pigs and cotton rats against a number of infecting doses of living rickettsias. The disadvantage of the method for large-scale production lies in the necessity of using the x-ray treatment and many thousands of mice. Should it be found desirable, however, to produce vaccine in this manner, I believe means could be found to circumvent such practical difficulties.

WORLD CONFLICT AND MEDICAL SERVICE*

JOHN M. PRATT †

CHICAGO

WE are at war! Slowly, it is seeping into our consciousness that it is a new kind of war in a new kind of world; that it is of such scope and of such proportions that no single human intellect can comprehend—even remotely—its final implications.

We shall win this war. It may be months long or years long, but, ultimately, the eternal verities for which we wage war will emerge triumphant. There are in prospect months, many months, of toil such as we have never known; sacrifice such as we have never imagined—tears and sweat and blood and heartbreak.

There can be no question concerning the deadliness of the peril or the necessity for unlimited sacrifice and undivided devotion. American medicine is trained in service—it is now steeling itself to its part of the gigantic task that lies ahead.

In October, 1941, the Procurement and Assignment Service was formally authorized as a governmental agency. The mechanisms and functioning of this vital, all-professional agency, headed by Dr. Frank H. Lahey, a distinguished member of your society, have been fully explained. Suffice it for me to say that physicians are beginning to understand that to meet the developing necessity every doctor and every medical student will be called on to contribute to the extent of maximum individual capacity. American medicine will make—already is making—its vital contribution without question—without qualification—without reservation.

Two phases or aspects of the operation of the Procurement and Assignment Service, however, should receive special consideration. A comparison should be made. Day by day, as moves were made to convert our production facilities, our resources, our manpower to make them available for an all-inclusive, all-out effort for total war, it became progressively more essential to establish arbitrary and effective controls. Our automobile industry has ceased to exist. Tires are not purchasable. We are becoming accustomed to cuffless trousers and rubberless girdles. Sugar is rationed. And it is fully understood that these are merely the beginnings of the establishment of controls that, eventually and quickly, will apply to all essential supplies. Each processor of goods

in the United States must secure his raw materials through a constantly tightening system of priorities. He is told what materials he can have, how much of them can be provided, how they must be utilized and what disposition shall be made of the finished product. There is no complaint. It is accepted that such steps and such controls are essential to the effort that must be made.

This is the significant and truly important fact. In this country we have now progressed to the point where the medical, dental and veterinarian professions—under the Procurement and Assignment Service—are the only nation-wide groups that operate on the basis of self-administration and self-discipline. In all likelihood, the establishment of this service on such a basis is the greatest achievement of and the greatest tribute ever accorded to these professions in the United States. It should be accepted on this basis—and physicians should see that their portion of it functions with such effectiveness that compulsory controls are rendered unnecessary.

That is the first phase. Organized medicine is one of three nation-wide groups—vital to the war effort—that have retained their autonomy, which is self-administering and self-disciplining.

The second phase is that of the elements of danger involved. Almost without exception, the leaders of medical organizations—the trustees of the American Medical Association, the members of the House of Delegates and the presidents, secretaries and other officers of state medical societies—make up the organization that carries on the all-important task of the procurement and assignment of physicians. It is expected that 40,000, possibly 50,000 physicians will be called to serve with the armed forces.

For a quarter of a century, to an ever-increasing degree, American medicine has been conscious of the threat of so-called “socialized medicine”—more accurately defined as state medicine or the political control of medical practice. It must be kept in mind that, if the war continues two or more years, with ever-deepening intensity, with a constantly accumulating need for devotion and sacrifice, which is to be expected, we shall have established the machinery and possibly may have developed the habit of providing for the distribution of medical care through an agency of government.

Under these conditions, medicine must remember—must be made to remember—the funda-

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 27, 1942.

†Executive administrator, National Physicians Committee for the Extension of Medical Service.

mental factors that are responsible for its present place of pre-eminence. Its scientific achievement, its technical effectiveness, its capacity to anticipate this great emergency need, its ability to make the contribution it has made and will make in war effort are the result of conditions and principles under which it has been permitted to function.

The basic tenet of American medicine has been that where there was disease a life was the issue. It mattered not whether prince or pauper was involved. If we are to make progress, this principle must be preserved and sanctified. The whole of men's concepts are in flux. This basic tenet may be lost or sacrificed unless we make a task of preserving it. This is the first part of an essential wartime task of the medical profession. It in no way militates against or in any way detracts from our contribution toward winning the war. It is of the most vital importance if we are to preserve the form and pattern of medical practice and the independence of the profession.

There is a second part to this really grave responsibility of the medical profession. It is of equal, possibly of greater, necessity that the general public be kept conscious of the general superiority of American medicine and of the greater relative effectiveness of our system of distribution of medical care.

In a very real sense, this is a function of the National Physicians' Committee for the Extension of Medical Service. It is my hope that I may leave with you a definite and lasting understanding of the "why" and the method of functioning of this all physician organization—the National Physicians' Committee. In the short time allotted, in all likelihood, this can be done most effectively by illustration. As a case in point—each week, every week, an editorial service is provided for more than twelve thousand weekly newspapers throughout the United States. Keep in mind that it is essential that the public understand what it—the public—has to gain or lose by substituting a political control of medical care for our system of independent medicine.

Always these editorials deal with health matters of current interest. The following are typical titles. "No Mass-Production Doctors"; "Science Must Know"; "The Eternal War"; "The War Against Disease"; "Socialism Doesn't Insure Health"; "Science and Freedom." Each editorial has a short, final paragraph dealing with the relative effectiveness of American medical service and our system of the distribution of medical care. For example: "The doctor is a soldier—a soldier fighting an everlasting war against disease and plague and death. Today medicine is mobilized to make

that fight even more effective." Another last paragraph: "Private medicine has made strides that can be best described as miraculous in controlling and eliminating the great bacterial killers. The final result is twofold—longer lives for the people and happier, fuller lives as well." Another: "We Americans have more doctors and better doctors than any other nation. We Americans, rich or poor, receive in sickness far finer care than any other human beings. That is the way the system of private medicine proves its soundness—by its final results." Another: "In this country, the level of public health is the highest ever attained in the civilized world. But even that great achievement doesn't satisfy the medical men. They mean to achieve far more in the years to come. That is the way the medical mind works. It never stands still. It must always look forward." One more last paragraph: "American doctors oppose political tinkering in the field of medicine which would in all probability make for retrogression, not progress, in medical science."

To illustrate more concretely the purpose and the method, on February 4, 1942,—note this date, approximately two months after the treacherous attack on Pearl Harbor,—the Council of the Massachusetts Medical Society unanimously adopted a vitally important resolution in connection with proposed amendments to the Social Security Act. In part, the resolution reads:

WHEREAS, It seems to be the intent of this legislation to finance this extension, in the case of the employed, by a tax of 1 per cent on payrolls, one half of which is to be paid by the employer and one half as a deduction from wages,

WHEREAS, The people of these United States are now heavily burdened and will be further burdened by our war effort,

WHEREAS, This is the first step in the direction of the complete control of the care of the sick by Government, and,

WHEREAS, Wherever such control has existed the quality of medical care has suffered, therefore, be it

RESOLVED, That the Council of the Massachusetts Medical Society in regular session, February 4, 1942, does hereby oppose any such extension of the present Social Security Law as is herein outlined

In connection with these same legislative proposals, the March 7 issue of the *Journal of the American Medical Association* carried a 2500 word editorial. I quote one short paragraph:

The American people are not averse to immense sacrifice—even to the ultimate sacrifice—if it will win the war. They should not be compelled, in the midst of such sacrifice, to consider radical proposals for changing the whole system of American living in health or in illness. The proposed expansions of the Social Security Act related to medical care should be considered in times when they can be given that type of

deliberate, meticulous consideration which carefully weighs every aspect of the problem concerned. Such proposals should not be submitted to the Congress and to the people in a period fraught with anxiety as to whether or not the nation itself will survive.

In this manner, clearly defined policy was established.

On March 23, the National Physicians' Committee provided its more than twelve thousand newspapers — with an estimated forty million readers — with an editorial, entitled "No Time for Wasteful Debate." It stated, in part, "It has been proposed that the Social Security laws be broadened in order to establish what would amount to a nation-wide system of compulsory sickness insurance." It quotes the above paragraph from the *Journal of the American Medical Association* and closes with this sentence, "This is certainly no time for debating a proposal which would take us a long way toward regimented, Europeanized, politically-dominated medicine."

On March 30, a second editorial, entitled "Not the Time," was provided for these forty million potential readers. The first and last two sentences of the editorial were as follows: "A definite campaign is underway to extend the Social Security Act to an extent never intimated when it was passed — and to an extent which would work a revolutionary change in American life." "This is not the time to dislocate a system of medical care which has produced such fine results. This is not the time to distract the attention of the people and the Congress with proposals which have no bearing on the incredibly difficult job of winning a war which comes ever closer to our own territorial borders."

On April 6, a third editorial was published. I quote the opening and concluding sentences: "While war news grips the headlines and the attention of the people, a movement is underway that would regiment the practice of medicine in this country." "This is not the time to debate a measure which would tend to make medical care a definite province of centralized government."

There was one more step in this systematic, continuing process. On March 24, the National Physicians' Committee was accorded the facilities of the approximately sixty radio stations comprising the Mutual Network for a fifteen-minute nation-wide broadcast. I quote from this broadcast:

American medicine believes that, at this time, there dare not be a division of effort. American medicine believes — and demonstrates its belief with deeds — that the war effort must be prosecuted with an unswerving singleness of purpose that will leave nothing to chance.

Now, unfortunately, there has been forced into this truly perilous situation legislative proposals which, if enacted into law, will take the first steps toward nul-

lifying the most sacred and basic concepts of the medical profession. Medicine, for itself, seeks nothing. Medicine asks for nothing save the preservation of conditions which enable physicians to apply their science and their skills to the best possible advantage. In the settlement of this grave issue the public has much to gain — with the alternative, the prospect of irreparable loss.

The broadcast quotes President Roosevelt on medical policy; it quotes the editorial in the *Journal of the American Medical Association*; and it concludes:

Eventually, after the war is won and the final victory is a reality, this vital issue can be reconsidered. If eventually some form of compulsory health or hospital insurance results — American physicians will accept the decision with a foreknowledge of its hampering, stultifying effect. For the time being, American physicians believe that there is one issue — now — winning the war.

This issue has been raised and must be met. It is not a matter of any selfish interest of the physicians of the United States. In a literal sense it is a matter of life and death. It directly affects one hundred and thirty million people who tomorrow or next week may be stricken with disease. At any cost, compulsion — any compulsion — should be avoided in the relationship between the patient and his physician. Tomorrow you may lunch with a friend — talk to him or her about this issue. You are a member of a club — make compulsory insurance the subject matter of discussion. Do this and you will do much — the one desire of American medicine is that the issue be really understood.

These circumstances have provided an opportunity for a concrete demonstration of the functioning of the National Physicians' Committee. There will be irreparable loss — if we fail to keep constantly in mind the fact that in the final analysis, *the public's opinion of the quality and effectiveness of medical service will become the deciding factor in the settlement of the problem.* They cannot know what it is, how it works, and of its relative effectiveness unless they are told. It has become definitely the responsibility of medicine to keep the public informed. In this instance, it was possible for the National Physicians' Committee to take the policy decision of the Council of your society and make it available to more than twelve thousand newspapers with nearly forty million readers and to carry the same message to hundreds of thousands, possibly millions, of radio listeners.

The first paragraph of the first document (*The Achilles' Heel of American Medicine*) ever published by the National Physicians' Committee reads:

The weak spot in American Medicine is in its singleness of purpose. Its greatest danger lies in the exclusiveness of its devotion to scientific improvement and technical effectiveness.

Under conditions now prevailing, the urge to the "limit of capacity service" is irresistible. Today,

American Medicine's greatest danger lies in the possibility of refusing or failing to keep in mind medicine's fundamental concepts during a period of abnormal crisis.

On this basis, the importance of the activities of the National Physicians' Committee has been multiplied greatly. Physicians must be made to keep in mind the fundamental factors responsible for its past achievements and its present unequalled effectiveness. The public—one hundred and thirty million people—must be kept aware of the fact that through our system of private medicine they have been the beneficiaries of the most effective and most widely and evenly distributed medical care that has ever been provided anywhere at any time. During the period of this greatest emergency, this is the primary function of the National Physicians' Committee.

During recent weeks,—since Pearl Harbor,—strong supporting committees have been organized: in Chicago, through fifteen branch societies; in Altoona, Lancaster, Williamsport and Philadelphia, Pennsylvania; in New York City—the Bronx, Richmond and Brooklyn—and in Buffalo, Rochester and Syracuse, New York. Many state societies have adopted resolutions providing for state-wide co-operation. It is hoped that with your commendation, the Council of your society may take official action in connection with approval of and support for the continuing work of the National Physicians' Committee, in order that during this trying period, when the necessity for controls is accepted and when regimentation is approved, we may be kept on the alert and constantly conscious of the elements of independence of action that are responsible for our past progress and our incomparable achievements.

Pittsfield Building

MASSIVE HEMATURIA OF RENAL ORIGIN*

GEORGE C. PRATHER, M.D.†

BOSTON

UNLESS one is aware of certain circumstances in medicine through personal experience or the experience of others, it is possible to arrive at false conclusions even when apparently sound reasoning has been used in formulating an opinion. As an example, profuse urinary-tract hemorrhages not infrequently occur from the necrotic or traumatized surface of a bladder tumor or from large, distended veins on the surface of an enlarged prostate; such hemorrhages are severe enough to fill and distend the bladder with blood and blood clot, and to cause acute urinary retention.

A hemorrhage of this magnitude from a renal lesion indicates that considerable blood has passed down the ureter to the bladder. If one remembers the physiology of renal and ureteral pain, the possibility for such a quantity of blood to pass down the ureter without causing renal pain owing to interference with drainage from the corresponding kidney seems rather remote. Yet the cases presented below demonstrate that renal bleeding sufficient to fill the bladder with blood and clots can occur without causing any discomfort in either kidney region.

In cases of severe urinary-tract hemorrhage without symptoms referable to the kidney region, there is always a temptation to open the bladder through a suprapubic incision, under the delusion that the

cause of the hemorrhage may well be found in the bladder or prostate. Knowledge that renal bleeding can produce an alarming collection of blood in the bladder without any symptomatic indication of the source of the hemorrhage should cancel this temptation, however, and should enjoin evacuation of the bladder through a rigid catheter, cystoscope or resectoscope, rather than by an exploratory incision. The endoscopic evacuation of the bladder should provide a medium sufficiently clear to permit observation of the ureteral jets or catheterization of both ureters, unless, of course, the source of the hemorrhage can be observed in the bladder or prostatic urethra.

The task of freeing the bladder of all clot is not always a brief or pleasant one. Not infrequently, an hour is spent in this procedure before a thoroughly satisfactory view of the bladder is obtained. For emptying the bladder of clot and blood in the circumstances under discussion, I have employed the sheath of either a No. 24 Fr. cystoscope or a resectoscope. Either the Ellik evacuator or a Janet type of syringe (glass barrel with steel plunger) can be attached to the distal end of these sheaths for alternate irrigation and suction. With the help of preliminary narcosis and local anesthesia, most patients can be handled without spinal or general anesthesia, although I see no objection to anesthesia for the procedure if the patient does not tolerate the maneuver with local medication.

*From the Urological Department, Boston City Hospital.

†Instructor in genitourinary surgery, Harvard Medical School; visiting surgeon for urology, Boston City Hospital.

After the bladder has been freed of its bloody content, cystoscopic observation usually reveals a bladder mucosa that is dull red, light absorbing, and lacking in normal luster. Following the inspection of the bladder itself for evidence of tumor, ulceration or other disease, it is advisable to watch the contractions of the ureteral orifices before they are catheterized. With severe bleeding from one kidney, careful observation of the ureteral orifices should disclose which kidney is at fault before the ureteral catheters are inserted. With this knowledge before catheterization of the ureters, the uncertainty of whether bloody urine draining from the ureteral catheter is due to true renal disease or the trauma of insertion is avoided. Catheterization of both ureters is desirable not only to provide pyelographic data of the bleeding kidney but also to demonstrate the integrity of the opposite one, should immediate removal of the diseased organ be deemed necessary.

Correct interpretation of the pyelogram of a bleeding kidney is notoriously difficult because of filling defects, which may be due to a blood clot in the kidney. However, the information obtained at the time of the emergency cystoscopy is essential either for a prompt diagnosis or for comparison with pyelographic data that might be obtained at a later date.

The immediate treatment naturally depends on whether prompt surgery seems to be necessary as a lifesaving measure to stop the hemorrhage or whether, after the bleeding has ceased, operation may be postponed until the problem has had further study and consideration. The general condition of the patient, the probable diagnosis and the state of the opposite kidney determine the appropriate treatment.

CASE REPORTS

CASE 1. W. G. (B.C.H. 983942), a 30-year-old man, was first admitted to the hospital on March 30, 1940, because of gross hematuria of a month's duration. Four days before admission, the hematuria became severe, and the patient passed large blood clots in the urine. There had been no pain in the kidney regions, but he described discomfort in the lower abdomen.

The past history was not significant, but the family history indicated exposure to tuberculosis in the household.

Physical examination disclosed no gross abnormalities except for the abdominal findings, which were those of a distended, tense bladder easily visible and palpable. The upper border of the bladder was at the level of the umbilicus. The whole lower abdomen was tender to palpation.

Laboratory data showed a red-cell count of 4,480,000 with a hemoglobin of 100 per cent, and a white-cell count of 8300. The nonprotein nitrogen was reported as 32 mg. per 100 cc. of blood.

An x-ray film of the chest was negative for tuberculosis.

Shortly after admission, the patient was catheterized, and the bladder evacuated of grossly bloody urine with a moderate number of clots. He was left on constant

drainage, and the hematuria disappeared spontaneously during the following 48 hours.

On April 5, cystoscopic study showed the left side of the bladder to be edematous, in addition to a small ulcer in that region. The mucous membrane of the remaining portions of the bladder revealed diffuse inflammation. The left ureteral orifice was deformed by edema and inflammatory changes. Both ureters were catheterized for

FIGURE 1. *Intravenous Pyelogram.*

There is an ulcerative lesion of the middle calyx of the left kidney. The lower left ureter shows an irregular dilatation.

specimens, and indigo carmine appeared from both ureteral catheters in 2½ minutes following intravenous injection. Intravenous pyelograms were obtained (Fig. 1).

A provisional diagnosis of left renal tuberculosis was made, and the patient was discharged from the hospital on April 10, pending report of guinea-pig studies of the kidney specimens.

The patient was readmitted on May 20, following autopsy of the inoculated guinea pigs, which indicated that the left kidney was positive for tuberculosis. On May 24, left nephrectomy was done through a lumbar incision. The kidney was easily exposed and delivered, and the ureter was ligated, bisected and tied approximately 10 cm. below the kidney pelvis. The pedicle was clamped, the kidney was removed, and the pedicle was securely tied. The wound was closed with a Penrose drain to the renal fossa. Convalescence was uneventful.

The pathological report described the weight of the left kidney as 120 gm.; several small, yellowish areas were scattered throughout the pyramids, pelvic mucosa and calyces. The microscopic diagnosis was tuberculosis of the kidney (Fig. 2).

On follow-up examination 1 year later, the wound was well healed, and the patient in good health.

CASE 2. J. D. (B.C.H. 967915), a 64-year-old man, was first admitted to the hospital on January 11, 1940, for acute urinary retention and gross hematuria. He had experienced urinary retention twice, but each time had resumed voiding after catheterization. He had recently passed grossly bloody urine and clots, but he had been unable to void for several hours prior to admission. At no time did the patient have any pain in the kidney regions.

Physical examination disclosed no pertinent physical findings except a distended bladder easily visible and palpable in the lower abdomen. There was no mass or tenderness in either kidney region. On rectal examination, the prostate showed benign enlargement.

Laboratory studies disclosed a red-cell count of 2,600,000 with a hemoglobin of 50 per cent and a white-cell count of 16,400. The nonprotein nitrogen was reported as 35 mg per 100 cc. of blood.

The patient was catheterized and placed on constant urethral drainage. Grossly bloody urine, with clots, was

FIGURE 2. Tuberculous of the Kidney.

This low-power photomicrograph of a section of the left kidney shows a large area of caseous necrosis, with tuberculous granulation tissue on the periphery.

obtained. On drainage, the urine remained somewhat bloody. Cystoscopy on January 14, 3 days after admission, still showed a quantity of bloody urine in the bladder, which was evacuated through the cystoscope. When a fairly clear medium could be established, it was thought that the patient probably had a malignant tumor on the posterior bladder wall, which obscured satisfactory vision of the bladder base and trigone. Neither ureter was catheterized, and no pyelographic studies were done. Following this examination, hematuria did not cease, and the patient's general condition was only slightly improved by two blood transfusions.

On January 20, a suprapubic cystostomy disclosed a very large blood clot and foul urine in the bladder. Intravesical enlargement of the prostate was observed, but no bladder tumor could be identified. A suprapubic tube was placed in the bladder, and the wound closed. Following the operation, lack of improvement was evident. The patient became septic, his general condition declined, and he

FIGURE 3. Bilateral Retrograde Pyelogram.

The lower calyx of the right kidney is shortened and partially obliterated.

expired about 6 weeks after operation. There is no indication on the record concerning whether or not the drainage remained clear.

At autopsy, the right kidney weighed 500 gm, and on microscopic section the upper pole was occupied by a tumor measuring 60 by 100 by 6.5 cm.; the grey red tumor extended into the pelvis and obstructed the ureter at its origin. More of the tumor could be seen in the veins and arteries of the kidney. The bladder mucosa was of increased thickness and red grey, but no tumor of the bladder could be demonstrated. The diagnosis was carcinoma of the right kidney.

CASE 3. M. C. (B.C.H. 978178), a 38-year-old man, was admitted to the hospital on April 6, 1940, with the diagnosis of acute urinary retention and gross hematuria. His general health had been good. The patient had experienced no urinary symptoms until 24 hours before admission, when he noticed blood in the urine. The hematuria continued with the passage of some clots. A few hours before admission, he was unable to pass any urine. His physician was called, but since an attempt at catheterization failed, the patient was referred to the hospital. There had been no complaint of pain in either kidney region.

Physical examination disclosed no pertinent findings except for examination of the abdomen, where a distended

bladder was easily visible and palpable. There was no tenderness or enlargement in either kidney region.

Laboratory studies revealed a red-cell count of 4,700,000 with a hemoglobin of 80 per cent, and a white-cell count of 12,300. The nonprotein nitrogen was reported as 23 mg. per 100 cc. of blood.

The patient was catheterized easily with a soft catheter, bloody urine and a blood clot from the bladder being evacuated.

Cystoscopy 2 days later showed the bladder mucosa to be red and edematous. Both ureteral orifices were

FIGURE 4. *Right Retrograde Pyelogram.*

The filling defect in the upper right ureter is due to blood clot. The lower calyx of the right kidney is distorted.

edematous, and dark urine could be seen coming from the left ureteral orifice. On the left lateral wall of the bladder, a small ulcer was visible. Both ureters were catheterized, specimens were obtained from each kidney, and a retrograde pyelogram was done. The pyelographic report indicated a filling defect 2.5 cm. in diameter involving the renal pelvis and superior calyx; this was thought to be tumor rather than blood clot.

On April 16, a left nephrectomy was performed through a left lumbar incision. The upper pole of the kidney was irregular and cystic to touch.

Pathological study of the removed kidney showed one entire pole to be cystic. In addition, there were five small, yellow nodules protruding from separate areas on the surface of the renal cortex. The microscopic diagnosis of the removed kidney was renal tuberculosis and chronic pyelonephritis.

Convalescence was uneventful, and the patient was discharged to a sanatorium on May 4. He was discharged from the sanatorium in good condition approximately 6 months later.

CASE 4. F. D. (private patient), a 64-year-old man, was admitted to a hospital on February 20, 1941, because of gross hematuria, which had begun 2 days previously. Several hours after he first noticed hematuria, it became difficult for him to pass any urine. His physician catheterized him, irrigated the bladder free of clot, and sent him to the hospital. At no time had the patient noticed discomfort in either kidney region. On arrival, he was comfortable and voided amber-colored urine easily.

The past history was irrelevant.

Physical examination disclosed no gross abnormalities. The blood pressure was 140/82. Abdominal palpation revealed no mass or tenderness. The bladder was not palpable or percussible. The external genitalia were nor-

FIGURE 5. *Renal-Cell Carcinoma.*

This section through the more compact portion of the tumor in the right kidney shows the tubular arrangement of the cells with only a moderate degree of vacuolization. The scantiness of the stroma is marked.

mal, and by rectal examination the prostate was normal in size and consistence.

Cystoscopy and a pyelogram were done the day following admission. The bladder appeared normal in all respects. No intravesical enlargement of the prostate was

noted, both ureters were catheterized easily, and clear urine drained from both kidneys. Good function of both kidneys was demonstrated by intravenous phenolsulfone phthalein. A bilateral pyelogram was taken. The pyelographic report failed to describe any dilatation or abnormality of the kidney pelvis or ureters (Fig 3).

Following cystoscopy, the patient voided clear urine for 36 hours, and suddenly he passed a large quantity of blood and blood clot through the urethra. Within 1 hour the bladder became distended with blood clot. At cystoscopy over 700 cc of blood and bloody urine was removed from the bladder by suction and irrigation through the cystoscope. After thorough washing of the bladder it was possible to visualize a long, stringy blood clot protruding from the right ureteral orifice. The right ureter was catheterized without difficulty, and a pyelogram made (Fig 4). This second pyelogram of the right kidney showed an apparent enlargement of the lower pole of the kidney that had the appearance of tumor.

On February 23 immediately after cystoscopy, a right nephrectomy was performed under spinal anesthesia through a right flank incision. The kidney contained a large, solid tumor at its lower pole. Intravenous glucose and a blood transfusion were given at the conclusion of the operation.

The pathological report of the excised kidney disclosed primary carcinoma of the kidney (Fig 5).

Convalescence was uneventful and the patient was discharged from the hospital on March 14.

Following discharge, he had a program of deep external radiation, which was completed on June 20. So far his

health has remained good and there has been no clinical evidence of recurrence of tumor either in the wound or at distant points.

Cases 1, 3 and 4 illustrate what is, I believe, the proper handling of the problems they present. Case 2 shows clearly the error that can easily be made—that is, interpreting blood clot in the bladder as evidence of bladder disease and proceeding with bladder surgery when the cause of the bleeding is a renal lesion.

CONCLUSIONS

Bleeding sufficient to fill the bladder with clots and cause acute urinary retention may be due to a renal lesion. The passage of a large quantity of blood from the kidney to the bladder can occur without causing discomfort in the kidney region or giving any clinical symptoms indicative of the source of bleeding.

If errors in treatment are to be avoided, careful evacuation of clot by endoscopic means must be done, and the source of the bleeding must be demonstrated. Occasionally, prompt nephrectomy is necessary as a lifesaving measure to avoid fatal hemorrhage.

CLINICAL NOTE

DETERIORATION OF MILK BY BACTERIAL GROWTH UNDER REFRIGERATION AT 40°F.*

FRANK E. MOTT † AND HENRY MAZER ‡
BOSTON

IN consideration of the possible effect of the adoption of delivery of milk every other day by dealers in Metropolitan Boston, it appeared desirable to ascertain what the change in the bacterial content of milk might be from day to day in a modern refrigerator at 40°F.

Such a study was undertaken, and the original in-

vestigation included Grade A milk-pasteurized, commonly called "Grade A milk," and Grade B milk-pasteurized, commonly called "milk-pasteurized." At the request of the Medical Milk Commission of Boston, Incorporated, the investigation was enlarged to include certified milk-pasteurized, produced under the supervision of the commission. The samples of milk were obtained from vehicles on the streets of Boston engaged in the delivery of milk during the period, March 3 to May 10, 1942. Table 1 shows the results of the study.

The colonies of bacteria were counted by the standard plate method of the American Public Health Association, with the plates incubated at 32°C.; the numbers listed are the arithmetical averages, which were used purposely so that the important effect of the lack of uniformity might not be lost.

After seventy-two hours in the refrigerator at 40°F., both Grade A milk-pasteurized and Grade B milk-pasteurized had such a growth of colonies

of bacteria from 1 cc. that their sale would be in violation of the law and standards of the Commonwealth of Massachusetts, which have been adopted for the protection of public health.

Certified milk-pasteurized, on the other hand, even after ninety-six hours in the refrigerator, still conformed to the bacterial standards and was perfectly safe for use as measured by present knowledge of the subject. After four days in the refrigerator at 40°F., both Grade A milk-pasteurized and Grade B milk-pasteurized had bacterial contents so great that their use might reasonably be expected to cause diarrhea and enteritis in children under six years of age.

To estimate the effect on bacterial growth of shutting off the refrigerator and the ensuing gradual rise in temperature, in one group of experi-

TABLE 1. Growth of Colonies of Bacteria from a Cubic Centimeter of Milk.

TYPE OF MILK	No. OF SAMPLES		No. OF COLONIES				
			ON DELIVERY	1 DAY AT 40° F.	2 DAYS AT 40° F.	3 DAYS AT 40° F.	4 DAYS AT 40° F.
Certified-pasteurized	22	Maximum	20	40	100	850	1,000
		Minimum	0	4	5	8	15
		Average	8	14	44	157	286
Grade A-pasteurized	12	Maximum	700	4,000	20,000	200,000	650,000
		Minimum	100	150	200	300	2,000
		Average	300	1,300	4,300	110,000	190,000
Grade B-pasteurized	12	Maximum	15,000	26,000	65,000	130,000	500,000
		Minimum	2,000	2,000	2,000	3,000	4,000
		Average	6,000	9,600	15,000	41,000	130,000

ments the refrigerator was turned off at the end of the second day, and samples of milk were taken then and at the end of the third day, when the temperature had risen to 53°C. The results are presented in Table 2.

Both Grade A milk-pasteurized and Grade B milk-pasteurized had undergone such an increase in bacterial growth that their use might have caused diarrhea and enteritis in young children.

TABLE 2. Growth of Colonies of Bacteria from a Cubic Centimeter of Milk before and after Stopping Refrigeration.

KIND OF MILK	AVERAGE NO. OF COLONIES	
	AFTER 2 DAYS AT 40° C.	1 DAY LATER (53° C.)
Certified-pasteurized	100	300
Grade A-pasteurized	5,000	540,000
Grade B-pasteurized	10,000	100,000

But certified milk-pasteurized conformed to the bacterial standards adopted for that grade of milk, and was still perfectly safe to use as measured by present standards.

In view of these findings, it is evident that the present conception of the inhibiting effect of refrigeration on bacterial growth in milk must be revised.

MEDICAL PROGRESS

DIABETES MELLITUS

ELLIOTT P. JOSLIN, M.D.,* AND HOWARD F. ROOT, M.D.†

BOSTON

STATISTICS

FOR 1939, the death rate for diabetes in the registration area of continental United States was 25.5 per 100,000, but in 1940 it rose to 26.6, with 35,015 deaths, the highest figures yet recorded. In 1941, however, there are indications from various sources that this upward rise is reaching a peak and that the deaths from diabetes have begun to decline from the previous rate. Thus, among the 17,000,000 industrial policyholders of the Metropolitan Life Insurance Company, the diabetic

physician, when he signs the death certificate, to minimize the importance of what is apparently the secondary cause of death—diabetes—or even omit it and register alone the actual cause, such as arteriosclerosis in its multiple manifestations, cancer, tuberculosis or similar but less frequent maladies.

The duration of life of diabetic patients is lengthening. The outcome of the first 10,000 patients (1898–1931) who consulted us on account of glycosuria has been investigated this year. The

*These figures were prepared by the Statistical Department of the Metropolitan Life Insurance Company. We are particularly indebted to Mr. Herbert H. Marks and Miss Edith Haldenstein.

mortality rate in 1940 was 29.5, and in 1941, 26.8 per 100,000. Similarly, drops, ranging up to 18 per cent, occurred in the reported rates for 1941 compared with those for 1940 in New York City (41.6 to 40.7), Chicago (38.0 to 31.1), Philadelphia (41.9 to 40.4), Boston (41.1 to 38.4) and Cincinnati (43.0 to 36.8).

The explanation of this decreasing mortality is at least threefold. In 1941, the good effects of the sulfonamide drugs became manifest in pneumonia and other infections—complications that have always taken a heavy toll of diabetic patients. Furthermore, the treatment of diabetes has steadily improved, largely owing to greater familiarity with the use of insulin and particularly to the protecting quality of protamine zinc insulin because of its prolonged action. Finally, this lengthening of life of the diabetic patient of itself, along with the better control of the disease, influences the

results, which have not hitherto been published, although they were cited in part at the meeting of the Association of American Physicians last May and formed part of an exhibit at the American Medical Association in June, are set forth in Table 1, in which for comparison are included data for earlier periods and also any deaths that were known among patients seen after 1931. These data are based on 6596 fatal cases that were seen up to and including April 20, 1942.

Fourteen and three tenths years now represents the average duration of life of recent fatal cases of diabetes seen one or more times in this clinic, in contrast to 4.9 years, which held before June 1, 1914. This figure deserves especial recognition because 30 per cent of the patients in 1940–1942 were already sixty years of age or older at the onset of their disease. With a gain of 3.6 years of life since the period, January 1, 1930, to December 31, 1936, based on fatal cases, it is reasonable to assume that the present expectancy of life in diabetes, as compared with that computed for our living and dead patients in 1938 by the Statistical Department of the Metropolitan Life Insurance Company, has risen from two thirds to nearly

Reprints of articles in this series are not available for distribution. But the articles will be published in book form. The current volume is *Medical Progress Annual Vol III 1941* (Springfield, Illinois: Charles C. Thomas Company, 1941, \$5.00).

*Medical director, George F. Baker Clinic, New England Deaconess Hospital.

†Associate in medicine, Harvard Medical School physician, New England Deaconess Hospital.

three quarters that of the population as a whole, and we hope that the recomputations will prove this to be true. The significance of this trend on later possibilities of diabetic patients for employment or life insurance should not escape notice. The duration of life in diabetic children with onset of the disease under ten years of age is low. It should be stated, however, that since August 7, 1922, only 68 of these children have died and that 800 are known to be alive; it is obvious that the duration of the disease in the latter will eventually prolong the average of the group as a whole.

A survival of less than five years was the rule prior to August 7, 1914; in fact, it included 66.8 per cent of all cases, but this percentage has now dropped to 13.0 (Table 2). The percentage of

TABLE 2. *Survival in 6596 Fatal Cases after Onset of Diabetes.*

ERA	SURVIVAL	
	LESS THAN FIVE YEARS	TWENTY YEARS OR MORE
	%	%
Naunyn	66.8	1.8
Allen	55.9	3.1
Banting		
Early	40.5	4.0
Late	22.5	10.2
Hagedorn		
Early	15.0	14.4
Late	13.0	19.2

patients surviving twenty years or more has risen from 1.8 in the earlier era to 19.3 today; 8.2 per cent survived even twenty-five years of the disease. There are also known to be 73 children, 71 of whom are alive, whose onset of diabetes occurred when they were under fifteen years of age and whose subsequent duration of life has reached twenty years or more.

Deaths from diabetic coma have fallen from 63.8 per cent in the Naunyn Era (1898-1914) to 3.3 per cent since January 1, 1940. Moreover, of the last 62 successive cases (October, 1940, to July 24, 1942) of proved diabetic coma, with a carbon dioxide combining power of 20 vol. per cent or below, under our immediate care at the New England Deaconess Hospital, there have been no deaths, and 12 of these patients were unconscious. Diabetic gangrene, which caused 8.5 per cent of the 1448 deaths from 1922 to 1929, was the cause of 4.7 per cent among 929 deaths from 1937 to 1940, although the average age of the patients rose approximately 8.0 years and the duration of the diabetes from 8.1 to 12.5 years.

SEASONAL INFLUENCE ON DIABETES

The *mortality* from diabetes is greater in the winter than in the summer. Dr. Herbert L.

Lombard¹ proved this by computing the deaths from diabetes in the United States for a year, using the deaths from cancer as a control. Thus, in December to May inclusive, the deaths from diabetes were 16,926 and in June to November inclusive, 13,661, whereas the comparable but adjusted deaths from cancer were 15,294 and 15,293. On the other hand, season had no influence on the *onset* of the disease. For this purpose, the data were limited to the cases of children seen in our clinic; the onset in adults is uncertain whereas in children it can be somewhat more accurately assigned. The figures for the children during the winter and summer months for the different types of onset are as follows: onset indefinite, 270 in winter and 267 cases in summer; gradual, that is, within two months, 347 in winter and 336 in summer; rapid, that is, within seven days, 80 in winter and 89 in summer; and sudden, that is, in the course of twenty-four hours, 91 in winter and 91 in summer.

ROLE OF HYPERGLYCEMIA IN DEVELOPMENT OF DIABETES

Perhaps the greatest contribution to the treatment of diabetes during the last year is the demonstration by Lukens and Dohan,² of the George S. Cox Medical Research Institute, University of Pennsylvania, that, in cats, hyperglycemia precedes the degeneration of the islands of Langerhans and that, by overcoming it within a period of three months after the production of diabetes in this animal by injections of anterior pituitary extract, one can reverse the process in the islands and can cure the animal. Nothing has better supported the orthodox treatment of diabetes than Lukens and Dohan's experiments in the forty years since Naunyn wrote that the patient with early, but apparently severe, diabetes if treated energetically would eventually do quite well, whereas the mild case if neglected would progress unfavorably. In previous progress reports,^{3,4} reference was made to the work of these authors and to that of others, but we consider the following paragraph of repetition justifiable, because of the crucial importance of the subject from the human therapeutic point of view.

The sequence of events revealing the significant relation of the pituitary gland and diabetes brings to mind the work of Cushing and Davidoff,⁵ who observed that 12 per cent of 100 cases of acromegaly had diabetes and 25 per cent showed glycosuria; this figure was later raised by Coggeshall and Root,⁶ in a series of 153 cases placed at their disposal by Cushing, to 17 per cent and 36 per cent respectively. Houssay's⁷ epoch-making experiments showed that the removal of the pituitary gland lessened the severity of diabetes in the

depancreatized toad, and that injection of pituitary extract into such animals made the disease worse. Evans⁸ observed glycosuria following the injection of the extract of the anterior pituitary in dogs. Young⁹ produced out and out diabetes in a dog by repeated injections of anterior pituitary extract, with demonstrable destruction of the islands of Langerhans. Best and his collaborators¹⁰ confirmed Young's work and proved that if the injections of pituitary extract were accompanied simultaneously by injections of insulin,—or, as later shown, by fasting or a high fat diet,—the development of the diabetes was prevented. Finally, and contemporaneously with the work at the University of Toronto, Lukens and Dohan² confirmed in a cat Young's original observation in a dog, but in the diabetically resistant cat it was necessary first of all to remove a portion of the pancreas, although not enough to cause glycosuria. These experiments emphasized the importance of hydropic degeneration of the beta cells as the pathologic state in the early stages of diabetes before atrophy, hyaline degeneration, fibrosis and lymphocytic infiltration occur. The studies of Lukens and Dohan confirmed Allen's¹¹ observation that hydropic degeneration in the partially depancreatized dog is reversible by fasting, and also by the administration of insulin (Copp and Barclay¹²). In severe diabetes, this was accomplished with insulin, and in milder cases of the disease, by a reduction in diet and, finally, by lowering the blood sugar with phlorhizin.

In their article, which deserves detailed study because it summarizes the work of the authors mentioned above and a few others, Lukens and Dohan² write

As a working hypothesis, the development of the permanent phase of diabetes may be stated as follows. The administration of pituitary extract results in (a) the production and maintenance of hyperglycemia, probably by its extra-pancreatic action, and (b) the damage to the pancreatic islands associated with this hyperglycemia, be it as cause or effect. A discussion of the possibility that injury to the islands may result from hyperglycemia must take account of two facts. These are the diminished liberation and content of insulin induced by pituitary extract and the increased production of insulin which follows elevation of the blood sugar in the normal animal. The results of Best, Campbell and Haist provide the most recent correlation between pancreatic insulin, blood sugar levels and island lesions. Regardless of the changes in insulin content, no permanent or irreversible damage to the islands has been produced by anterior pituitary treatment except when there is concomitant hyperglycemia. In addition, in the case of the cat, the high blood sugar persists after stopping pituitary extract even though the pancreatic lesions are still reversible. This suggests that hyperglycemia maintains the island damage (a vicious cycle). Stated in brief, the hypothesis that the elevation of the blood glucose is an important factor

in the causation of island pathology is supported by the following general observations: (a) Partial pancreatectomy or pituitary extract do [sic] not cause island lesions in the absence of hyperglycemia and (b) each leads to hydropic degeneration after hyperglycemia has been present for a week or two. (c) The elevation of the blood sugar by perfusion has resulted in early lesions of the islands. (d) The islands are restored by various types of treatment which return the blood sugar to normal levels.

These authors emphasize the need for an open mind concerning the pathogenesis of diabetes. This is because Long,¹³ in New Haven, and Ingle,¹⁴ in the Cox laboratory, found almost no hydropic change or atrophy of the islands in rats subjected to marked hyperglycemia for periods of from two weeks to several months, although such findings have been reported by Friedman and Marble.¹⁵

EXPLANATION OF TALL DIABETIC CHILD AND FAT DIABETIC ADULT

Young¹⁶ comments on the emphasis laid by our group¹⁷ on obesity in adults and overheight and precociousness in children as a prelude to the onset of diabetes. He cites our query—"In the child, growth is vertical, in the adult it is lateral. Is not each type of endocrinal origin?"—and proceeds to solve it in a series of experimental investigations, concluding "that a positive answer might be given to Joslin's question in terms of pancreatic hypophyseal balance."

Young refers to the first demonstration of the diabetogenic action of anterior pituitary extract in normal animals by Evans,⁸ in which two puppies treated daily with a growth promoting preparation of ov pituitary gland increased twice the weight of control animals and developed polyuria and glycosuria. The pituitary extract that Young used in the causation of diabetes in the adult dog was accompanied by a growth promoting substance. Others have also shown a similarity in properties between the growth promoting and diabetogenic substances. Young notes that Evans, for the growth hormone, and Houssay,⁷ for the diabetogenic substance, emphasized the value of using absolutely fresh glands and carrying out all procedures at low temperatures, and he therefore considers it surprising that more cases have not been recorded of the development of a diabetic condition in puppies in which gigantism has been produced by treatment with growth promoting pituitary extracts.

Recalling that, with the adult dog effectively treated with diabetogenic extract, eventually a refractory state developed, during which the symptoms of diabetes disappeared until the daily dose of extract was increased, Young points out the

possibility that the puppies treated with growth hormone did exhibit a transient response to the diabetogenic action of the extract but subsequently became refractory to it while retaining a sensitivity to its growth-promoting effect. In a series of experiments utilizing evidence, already furnished by Evans and by Mirsky,¹⁸ that growth-hormone preparations induce retention of nitrogen and that this nitrogen-retaining action may be mediated by the islands of Langerhans of the pancreas, he investigated the relation between the nitrogen-retaining and pancreatropic actions of anterior pituitary extracts in permanently diabetic animals in which some islet tissue remained.

Young observed that with normal cats and normal dogs an increase in body weight is associated with induction of a diabetic condition produced by the administration of crude pituitary extract, and he points out that Ogilvie¹⁹ presented quantitative evidence that human infants have a greater amount of pancreatic islet tissue in proportion to body weight than adults. Indeed, Langfeldt,²⁰ years ago, noted that partially depancreatized puppies, which had been deprived of a sufficient portion of pancreas to provide a reasonable expectation of the appearance of diabetes in an adult dog, not only were free from all symptoms of diabetes for many months after the operation but also, in some cases, showed an increase of sugar tolerance; however, the sugar tolerance eventually declined, and evidence of progressive and fatal diabetes became manifest.

Space does not allow presentation of Young's experiments in detail, but his own summary is as follows:

When puppies are treated daily with doses of crude pituitary extract greatly in excess of those required to produce diabetes in adult dogs, they respond with an increased growth rate but do not exhibit symptoms of diabetes. When one puppy was treated daily for nearly five months it eventually became intensely diabetic, and then stopped growing despite continuation of treatment.

When adult dogs that have been rendered permanently diabetic by a short period of pituitary treatment are given a single injection of pancreatropic pituitary extracts, which produces no detectable diabetogenic activity in normal adult dogs, the response may be a transitory attenuation of the diabetic condition with nitrogen retention and increase of body weight or an exacerbation of the diabetes with loss of nitrogen and of body weight; intermediate responses were also obtained. These differences in response are believed to result largely from differences in functional capacity of pancreatic islet tissue.

It is suggested that an increase in body weight, associated with an increase in function of the pancreatic islets, can be regarded as neutralizing, for a time at least, the diabetogenic influence of the anterior pituitary gland. It is therefore possible that the excessive weight of the adult diabetic patient and the abnormal height

of the diabetic child (White) indicate an increased pituitary function which may be of temporary duration only, and of which the diabetogenic action may be completely masked for a time by a protective increase in pancreatic islet activity, induced by the pancreatropic action of the gland. Such a condition might lead first to an increase in the mass of the body and eventually to diabetes.

INFLUENCE OF ESTROGENS AND ANDROGENS ON CARBOHYDRATE METABOLISM

The influence of the estrogens and androgens on carbohydrate metabolism in normal and diabetic animals continues to excite curiosity. Apparently, the effects observed in the intact animal are quite different from those in animals partially or wholly diabetic, and the results in human beings are rather difficult to interpret. Griffiths, Marks and Young,²¹ using normal rats in fasting condition, were able to show that the administration of estriol and estradiol, like that of diethylstilbestrol, promotes glycogen storage in the liver, whereas estrone and testosterone do not. Parallel increases in the amount of insulin in the pancreas also occur. Similarly, Fraenkel-Conrat et al.²² were able to produce increase in pancreatic insulin when prolonged estrinization of normal rats was carried out. They conclude that two types of evidence favor the assumption that the activity of estrogens in elevating the pancreatic insulin is due to the pituitary gland — namely, the pituitary glands of such rats, when implanted in other animals, elevate the pancreatic insulin content, whereas the glands of untreated rats do not show this activity. Moreover, estrogen, which raises the pancreatic insulin content in normal rats, does not have this effect in animals whose pituitary glands have been removed. On the other hand, when Ingle²³ administered stilbestrol to partially depancreatized rats on a constant medium-carbohydrate diet, severe glycosuria and hyperglycemia occurred in all cases. Similar results were obtained with dihydrostilbestrol, estradiol and equilin. Also, large doses of testosterone and methyl testosterone were weakly diabetogenic. In another series of studies, Ingle²⁴ showed that the administration of 17-hydroxy-11-dehydrocorticosterone to normal rats that were force fed with a high-carbohydrate diet caused hyperglycemia, glycosuria and an increased excretion of nonprotein nitrogen, with atrophy of the testes and thymus gland. These results seem to be confirmed by the experiments of Long,²⁵ which suggest that stilbestrol behaves somewhat like the adrenocortical hormone. In the studies by McCullagh,²⁶ the use of methyl testosterone in rabbits produced a low-carbohydrate tolerance, whereas testosterone propionate did not lower the carbohydrate tolerance. The favorable effects of methyl

testosterone in adult diabetic patients reported by some authors has not been confirmed by others.

In reporting the clinical use of stilbestrol in 79 diabetic women in the premenopausal, menopausal and postmenopausal years, Beardwood²⁷ was able to reduce the insulin dosage by an average of 11 units in 36 cases. In a group of 14 patients treated with large doses of Progynon B, an average reduction of 18.3 units in insulin dosage occurred in 8 patients. He concluded that estrogenic substances cannot be considered a substitute for the well established standard treatment of diabetes with diet and insulin, but that these special preparations had a stabilizing effect in a special group whose diabetes was very labile.

SPECIES DIFFERENCES IN DIABETES FOLLOWING PANCREATCTOMY

Species differences in diabetes following pancreatotomy have been emphasized by Mirsky.²⁸ The greatest rise in blood sugar is observed in cats, monkeys, man, owls, snakes, dogs and rabbits in decreasing order. Animals like the duck and the chicken, on the other hand, show almost no rise of blood sugar after pancreatotomy and, indeed, no increase in blood acetone. One might say, therefore, that human diabetes is a species diabetes differing in some respects from that observed in other animals.

RESISTANCE TO INSULIN AND ALLERGY

Resistance to insulin associated with allergy to insulin has been reported in a number of cases, but it may have greater significance than has yet been realized. It is possible that such frequent although not necessarily extreme cases of insulin resistance as occur during certain types of infection may be due really to manifestations of allergy. In 2 recent cases at the New England Deaconess Hospital, allergy to insulin was associated with insulin resistance and the occurrence of specific insulin precipitins in the blood. In one case, both asthma of long duration and an acute infection were present in a patient whose diabetes rapidly became so severe that actual, serious acidosis occurred. It is possible that the acute infection stirred up general antigenic manifestations in the body and that, as a result of this change, insulin resistance occurred. Lowell²⁹ reports studies on a forty-three year old woman who had severe urticaria following injections of crystalline and regular insulin. In this case, it was found that the patient was very resistant to ordinary crystalline insulin so that an injection of 30 units intravenously caused a slight rise in the blood sugar, followed by a fall to a point only slightly below the fasting level. On the other hand, when 30 units of insulin prepared from human pancreas were

injected intravenously, a fall in blood sugar took place so rapidly that a hypoglycemic reaction occurred at the end of ninety minutes, when the blood sugar was 59 mg per 100 cc in contrast with the fasting blood sugar of 330 mg. However, a marked allergic reaction, which was characterized by urticaria and constriction in the throat, occurred within fifteen minutes after injection of the human insulin. Tests with mice for insulin-neutralizing antibody showed that the patient's serum neutralized crystalline insulin, because the addition of serum to insulin when injected into the mice prevented a hypoglycemic reaction, such neutralization did not occur when human insulin was used. By a passive transfer test, it was shown that skin sensitizing antibodies were present in repeated specimens of the patient's serum over a period of six months. It was possible to sensitize normal skin to crystalline and human insulin by the injection of serum from the patient in dilutions varying from 1:16 to 1:64.

It is clear, therefore, that allergy to insulin can exist in the absence of resistance, and that resistance can exist in the absence of allergy. In Lowell's patient, resistance to crystalline insulin but not to human insulin was present. The patient reacted allergically to both crystalline and human insulin, and skin sensitizing antibody was present for both. The patient's serum, therefore, contained an antibody for insulin, which protected mice from a lethal dose of crystalline insulin but failed to protect against human insulin. It may be concluded that two antibodies were present in the patient's serum: an allergic antibody, which conferred sensitivity on normal skin, and an insulin neutralizing antibody, which was capable of destroying the physiologic effect of crystalline insulin.

Hyperinsulinism in a forty-year old man was treated successfully by Allen³⁰ with a diet high in carbohydrate in contrast to the diet sometimes recommended, in which a high protein content is used in the hope that a slow liberation of carbohydrate will counteract the hypoglycemia. The patient's weight was allowed to fall from 237 to 228 pounds. The blood sugar values after a glucose tolerance test ranged between 41 and 51 mg per 100 cc. Allen points out that the hyperinsulinism in any patient who can be treated by a high protein diet must be very mild. As an incidental experiment, he tried to improve the circulation of diabetic patients with deficient arterial blood supply by the administration of Antuitrin S, without favorable results.

RESPIRATORY QUOTIENT AND CARBOHYDRATE METABOLISM

In recent unreported studies carried on jointly by the Carnegie Nutrition Laboratory and our clinic, the results obtained after the administra-

	\$4455.87
Balance January 5, 1942	97.66
	<hr/>
	\$4553.53

The Society is in good financial condition, with a balance of \$97.66 on January 5, 1942. The Benevolence Fund on the same date amounted to \$1385.69. Of this amount, the principal is \$991.19, and the accrued income is \$394.50. During the past year, we have received \$75.00 for this fund from the women's auxiliaries of the following counties:

Merrimack	\$35.00
Strafford	10.00
Rockingham	20.00
Coos	10.00

We gave \$100.00 to the State Auxiliary to cover in part the expenses of its meeting last May.

There were two unpaid bills on January 1, 1942, owing to the fact that our expenses were heavier than usual at the one hundred and fiftieth anniversary. These bills, whose total amount was \$400.08, have since been paid.

One officer and one former officer of the Society have died since our most recent meeting: Robert M. Deming, of the Committee on Tuberculosis, died on January 28, 1942, and Frank E. Kittredge, a former president, died on July 8, 1941.

The President chose Ralph W. Tuttle, of Alton, for Anniversary Chairman.

A year ago, the House of Delegates made the following recommendations, which have been carried out:

Dues were remitted for members who during any part of the year were in the Service.

The New England Medical Council was eliminated from the standing committees.

A Committee on Public Health was appointed, which has been co-operating with the State Board of Health.

The Committee on Child Health and the Committee on Maternity and Infancy have been made standing committees instead of special committees.

Fifty dollars was given to the Cancer Committee for its work.

The Committee on Public Relations and the Committee on Medical Economics conferred with Mr. Sulloway and have written an enabling act to cover the cost of medical care.

The Committee on Medical Economics conferred with the Farm Bureau about sickness insurance for farm families, but the Farm Bureau has apparently dropped the plan and has shown no recent interest in putting it into effect.

The Committee on Medical Relief has been disbanded. Its work has been referred to the Committee on Medical Economics.

Since the last annual meeting, the Benevolence Fund has received \$1.00 from every member who has paid his dues.

On July 9, 1941, the Trustees removed \$3000 of the Benevolence Fund from the Savings Bank and invested this amount in United States Savings Bonds. On the same date, \$1000 was removed from the General Fund to pay the expenses for the one hundred and fiftieth anniversary.

Dr. Adolphe J. Provost, of Manchester, was appointed a member of the Medical Advisory Committee on Eye Diseases to co-operate with the State Department of Welfare.

I have referred to the Committee on Communications and Memorials two problems of membership. One of our elderly members has been afflicted with cerebral thrombosis and would like to become an affiliate member. He

is, however, one of five members who joined the Society before a county society had been formed in his territory. The by laws make it compulsory for a county society to recommend a man for affiliate membership before the House of Delegates can vote on such a matter.

The other case concerns a doctor in another state who was originally a resident of New Hampshire. One of the county societies elected him an honorary member, but he desires to pay his dues. Some definite conclusion should be reached on these two cases and on similar cases that may arise in the future.

We have eleven standing committees and two rotating committees. It seems inconsistent to have the Committee on Medical Economics and the Committee on Medical Education and Hospitals rotate each year. Should not these committees be standing committees?

CARLETON R. METCALF, *Secretary Treasurer*

On motion duly made and seconded, it was voted that the Secretary be instructed to read the communication from the Treasury Department, Bureau of Narcotics, before the Society.

Dr. Dye spoke as follows:

An agent of the Bureau of Narcotics visited the State Board of Registration in this connection a couple of days ago. I believe last year the House of Delegates decided against recommending approval of the Uniform Narcotic Act for New Hampshire, because of the amount of red tape engendered in carrying out such an act. However, it is obvious from this letter and from the report unofficially made to us by the representative of the department that the doctor is liable for all the representations that come to him in the way of dispensing narcotics.

At the moment, there is nothing in the state law that will enable the State or a federal prosecutor to hold, in the state's name, an addict who falsely obtains, by the nature of fraud or intention of fraud, a prescription for narcotics from a licensed practitioner in the State. I should like to recommend either for discussion or for a motion, as is seen fit, that the House of Delegates recommend to the State that an amendment be passed to our present narcotic law, that any person who secures a narcotic prescription from a physician, with the intent of actual fraud or intent to fraud, shall be prosecuted by the State.

I believe that would help the situation tremendously. Case after case was reported to us in which a smooth talking person, more or less of a confidence man, would approach some member of our profession in the State and would secure from him a large narcotic prescription. This person, in turn, would go to a drug store and purchase the narcotics. He would be apprehended by a man who represented, as an investigator, the Bureau of Narcotic Control, and found that this prescription was not necessary for him. But, according to our state law, there was nothing that the investigator could do to hold this person, who had secured a prescription by fraud. The only thing in the law would be to take some punitive measure against the physician who issued the prescription.

Therefore, the duty falls on the physician in this state as well as the pharmacist, concerning whether anything shall be done, or any prosecution shall be made for the violation of this law.

Since we have no uniform narcotic act, and since any smooth confidence man may come into the State, get a prescription and have it filled and not be liable, we

are more or less open to having many of these fraudulent addicts come here and put us on the spot, with regard to prosecutions.

Therefore, I believe that some action should be taken by the House of Delegates on this recommendation.

Dr. D. G. Smith seconded Dr. Dye's motion and stated that there are forty-three or forty-four states in which the man who obtains the narcotic or prescription is liable for prosecution. New Hampshire and Vermont are two of the states in which there is no penalty for a man coming in and obtaining a prescription. The result is that such persons are already beginning to flock into New Hampshire and Vermont, buying the morphine and taking it to Boston and peddling it there.

Dr. Sycamore asked if there were a uniform narcotic law that is recommended by the Federal Bureau.

Dr. Dye answered that a uniform narcotic act came up before the House of Delegates last year and was voted against because it entailed a good deal of red tape. It would require a full-time man in the Health Department, with much expense to the State. There would also be a considerable amount of red tape for each physician regarding making out of forms and so forth. The State Board of Health is more or less against a uniform narcotic act; it does not believe that the State is large enough to warrant such a law. It is believed that some amendment to the present law, to make persons who obtain prescriptions by fraud liable to prosecution, would be sufficient.

The President asked if that released the doctors from their responsibility.

Dr. Dye replied that it did not but that, at the moment, the addict is not held to prosecution at all, whereas the doctor has all the responsibility.

Dr. Sanders asked whether everything could be covered so that the addict could not escape the responsibility and how fraud on his part could be proved.

Dr. Metcalf answered that the amount obtained was proof. For example, when a man buys 100 tablets of morphine, $\frac{1}{2}$ grain each, he is considered an addict.

The motion was carried.

The Committee on Officers' Reports commended the faithful and efficient work of the Secretary-Treasurer and recommended that, at the next revision of the by laws, the Committee on Medical Economics be changed from a rotating to a standing committee.

Dr. D. G. Smith suggested that the Committee on Medical Education should also be changed.

Dr. Dye moved that both committees—the Committee on Medical Education and Hospitals and the Committee on Medical Economics—be made standing committees.

Dr. Sycamore recommended that at the next revision of the by-laws, the Committee on Medical Education and Hospitals and the Committee on Medical Economics be changed from rotating committees to regular standing committees.

Dr. Dye suggested that this matter be referred to the Committee on Constitution and By-Laws, with the request that it be reported the following day.

Dr. Sycamore accepted the amendment.

This motion was duly seconded and was carried.

Because of the amount of business to be transacted, it was voted to omit the reading of the councilors' reports.

Reports of Councilors

BELKNAP COUNTY

The Belknap County Medical Society held six meetings from November to April inclusive. The meetings were all well attended, and the excellent quality of papers was maintained. A different member was responsible for each meeting.

The Society lost one member by death and gained four new members.

C. S. ABBOTT

CARROLL COUNTY

The Carroll County Medical Society held its meetings as usual.

Our membership is small but our spirit is excellent.

One member is now in the Army Medical Corps, and of course, others may follow.

Our spring meeting has been postponed to a later date than usual because of the absence of our President, but this meeting will be held early in the summer.

CHARLES E. SMITH

CHESHIRE COUNTY

The Cheshire County Medical Society held two meetings during the past year. At each meeting, papers were read by visiting men. Each paper was discussed at length and this added much interest to the meetings.

We have had no increase in membership in the past year. One member is in service at the present time, and several more are awaiting call.

JOHN J. BROSNAHAN

COOS COUNTY

The Coos County Medical Society has not met this year. We are expecting a grand meeting this spring after the State Society meeting. On this account, I have little to report. I am hoping for more interest among the profession this coming year.

RICHARD E. WILDER

GRAFTON COUNTY

The annual business meeting of the Grafton County Medical Society was held at the Grafton County Hospital, North Haverhill, on October 9, 1941. Election of officers took place, and nine new members were received.

A group discussion was led by W. F. Putnam, of Lyme, on "Pitfalls of Medical Practice."

Three other meetings were held during the year. On December 11, the Society met at Hale's Tavern, Wells

River, Vermont, for dinner, and a group discussion on "Common Respiratory Infections" was led by E. C. Campbell, of Woodsville.

The meeting of January 29, 1942, was held at the Littleton Hospital. A discussion on "Uterine Hemorrhage" was led by H. C. Pickwick of Lisbon.

On February 26, the society convened again at Hale's Tavern, Wells River, Vermont. The discussion on "Uterine Hemorrhage" was continued.

The programs of these meetings dealing with everyday problems of general practice were arranged purposely to stimulate discussion and active participation of a larger number of members.

A. W. BURNHAM

HILLSBOROUGH COUNTY

The Hillsborough County Medical Society during the last year has had the largest membership since it was founded. We have at present 146 members.

At our meeting in Manchester, November 18, 1941, we had two very interesting papers, one by Dr. Alfred L. Frechette, on "Venereal Disease Problems in New Hampshire," and one by Dr. Thomas J. Anglem, on "Chemotherapy in Surgery." During the morning session, Dr. Charles H. Parsons gave a very detailed talk on "Medical Organization for Civilian Defense" in this state. This was of great value, and I understand that practically every town in Hillsborough County has a medical setup as part of its civilian defense.

A spring meeting was held at the Nashua Country Club, where Dr. Dolloff, president of the New Hampshire Medical Society, spoke, and where papers were presented by Dr. Charles H. Rammelkamp and Dr. Otto J. Hermann, of Boston.

A very largely attended meeting was held at Alma's Tea Room, Manchester, on April 28. Dr. Deering Smith gave a complete outline of the Procurement and Assignment Service. Interest ran high, as shown by the fact that three hours were taken up in the presentation and discussion of this subject. Dr. W. D. Thibodeau, president of the Hillsborough County Medical Society, complimented Dr. Smith on his excellent presentation.

I am of the opinion from my observation that more interest is being taken in the county meetings. This is shown by an increase in membership and the attendance, which is about fifty at each meeting.

CLARENCE O. COBURN

MERRIMACK COUNTY

The Merrimack County and Center District Medical Society has held four meetings during the past year.

At a meeting on July 2, 1941, held at the Franklin Country Club, Dr. Lewellys F. Barker, professor emeritus of medicine at Johns Hopkins University School of Medicine, spoke on "Heredity." Dr. R. J. Weissman, of Franklin, was voted into membership.

On October 8, a meeting at the Eagle Hotel, Concord, was addressed by Dr. Champ Lyons, of the Massachusetts General Hospital, who spoke on "Chemotherapy." He recommended sulfadiazine as the drug of choice. Dr. W. H. Norton, of Andover, was admitted to membership. It was voted to send \$100.00 to the National Committee for Extension of Medical Service.

On January 7, 1942, the annual meeting was held at the Eagle Hotel. Dr. Edward Putnam was elected president, Dr. Philip Forsberg was elected vice-president, and Dr. Warren Butterfield was re-elected secretary-treasurer. Dr. Charles H. Dolloff, president of the New Hampshire Medical Society, spoke briefly. With Dr. Carroll Cilley,

county commissioner, as guest, the present day relief problems were discussed at considerable length. Drs Bland, Morrity and Philbrook, of the State Hospital Staff, were elected members of the Society.

On April 1, 1942, a meeting was held at the Eagle Hotel. At the request of the Auxiliary, future meetings are to be held on the first Tuesday of the month. Dr Deering Smith, of the Procurement and Assignment Service, spoke on medical enlistments. In recognition of his long membership and service to the profession, Dr Chancey Adams was presented with a suitable gift.

HENRY H. AMIDEN

ROCKINGHAM COUNTY

The annual meeting of the Rockingham County Medical Society was held at the Mitchell Memorial Hospital, Brentwood, on December 17, 1941. Officers for the following year were elected, and four new members were admitted. Luncheon was served by the county commissioners and superintendent.

The afternoon session was devoted to a discussion of the medical defense setup in this county. In outlining plans for the organization of medical defense units, consideration was given to the necessity of some unification of system and the recommendation was made that each community take suitable steps regarding equipment trained workers and physicians at hand.

The spring meeting of the society was held at Exeter Hospital on April 28, 1942. Twenty-eight members were present. At the business meeting, following a discussion concerning the methods used and the extent to which chiropractors were encroaching on the practice of medicine in Rockingham County, a motion was adopted instructing the county's delegation to bring this matter to the floor of the State Society House of Delegates for action.

After further discussion, a motion was adopted instructing the County Delegates to bring to the attention of the State Society House of Delegates the problem of medical officers in the United States Navy practicing private medicine while on duty. There was evidence that such practice was occurring at Portsmouth Navy Yard. It was further requested that a ruling on this matter be obtained from the Navy and War departments from the Commandant, Portsmouth Navy Yard, and from the State Board of Registration in Medicine. One new member was admitted.

After luncheon at the hospital, Dr D. G. Smith of Nashua, Chairman of the New Hampshire Procurement and Assignment Service, gave a detailed resume of the present status demands of the Government on New Hampshire physicians for war service. He stated that the quota for the next sixty days was fifty doctors, and warned that more would be called for, urging full co-operation to help fill the immediate quota of the State under the direction of the medical profession itself, rather than under assumption of powers of draft by the government authorities.

CLEON W. COLE

STRAFFORD COUNTY

The Strafford County Medical Society had for the year 1942 thirty-four active and six affiliate members.

The annual meeting was held on October 22, 1941, at the University Commons, Durham, New Hampshire. It was the one hundred and twenty-fourth annual meeting of the society and was attended by twenty-three members and a guest. Dr. Charles H. Dolloff, president of the

New Hampshire Medical Society, presented informative material regarding the Newer Treatments of Mental Disorders.

A special meeting of the society was held on March 8, 1942, at the American House, Dover, New Hampshire. Twenty-one members were present. The purpose of this meeting was to discuss and act on an increased fee table for medical services in Strafford County, the fees then existing being lower than the usual fees elsewhere in New Hampshire. A new minimum fee schedule was adopted and went into effect on March 15, 1942.

The spring meeting was held at the new Frisbee Memorial Hospital in Rochester, New Hampshire, on April 29, thirty-one members and guests being present. After the usual business meeting, Dr. Samuel Levine presented an excellent paper on Heart Disease Electrocardiography and the General Practitioner, a lecture of great service to those present. Dinner was served by the hospital authorities and the local doctors conducted the out-towners on a tour of the hospital. Rochester may well be proud of this beautiful gift to their community.

There were no deaths among our members during the fiscal year.

Dues were all paid promptly and disbursed to the state society treasurer on February 3, 1942.

J. A. HUNTER

SULLIVAN COUNTY

The Sullivan County Medical Society enjoyed its usual activity during the past year. All physicians practicing in the county are members of the society, and the percentage of attendance at meetings is always high.

At the annual meeting held in Claremont, we were favored in having as our guest Dr. Charles H. Dolloff, of Concord, president of the New Hampshire Medical Society, who spoke on Medical Defense and other timely subjects.

In addition to the election of officers for the coming year, there was a scientific program with free discussion by many of the members.

Luncheon was served at the Claremont General Hospital. Our next meeting will be held at Charlestown during the summer.

EMERY M. FITCH

In the absence of Dr. Woodman, Dr. Dye stated that the members of the Committee on Amendments to the Constitution and By-Laws knew of no necessary amendments to the constitution and by-laws that should be brought up for this year.

In the absence of Dr. Stewart, Dr. Sycamore read the report of the Committee on Child Health.

Report of the Committee on Child Health

The Committee on Child Health co-operated in the presentation of a series of radio talks on various aspects of child health, given under the auspices of the New Hampshire Congress of Parents and Teachers and the New Hampshire Pediatric Society. These were broadcast over Station WFEA, beginning in October and continuing into February.

At a meeting on February 18, the recommendations of the Children's Bureau regarding immunization of children as a war measure were considered as they applied to New Hampshire. It was agreed

1. That it would be desirable to have all children over nine months of age immunized against diphtheria and smallpox;

2. That it would be better to defer any large-scale attempt at immunizing against tetanus until a uniform system of tagging such children could be worked out for the country as a whole;

3. And that immunization against typhoid fever could be deferred until such time as evacuation of cities became necessary, and could then best be done at evacuation centers as a mass procedure.

COLIN C. STEWART, *Chairman*

TRAVIS P. BURROUGHS

FRANKLIN N. ROGERS

Dr. Sycamore stated that the Committee on Officers' Reports commended as a valuable educational method the activities of the Committee on Child Health in co-operating in the presentation of radio broadcasts.

The conclusions of the committee regarding immunization of children as a war measure were approved, and it was recommended that the House of Delegates instruct the Committee on Child Health and the Committee on Public Health to confer with and co-operate with the appropriate State and Federal agencies, with a view to carrying out the immunization against diphtheria and smallpox of all children over nine months of age.

Dr. Sycamore moved the adoption of this portion of the report.

This motion was duly seconded and was carried.

Report of the Committee on Public Health

The Committee on Public Health is a new one, being first elected in 1941; no one on the committee knew its duties or its function. Communication with Dr. Metcalf, secretary of the New Hampshire Medical Society, concerning its duties referred us to Dr. Burroughs, of the State Board of Health, and after some thought we are of the opinion that we are liaison officers between the New Hampshire Medical Society and the State Board of Health.

We have had five meetings in Concord. The first was held at the office of Dr. Burroughs at the State House on September 26, 1941. Drs. Burroughs, Frechette, Vintner, Powers and Smart were present. The discussion was concerned mainly with whether or not the New Hampshire Medical Society, as represented by the Committee on Public Health, would recommend or sanction the Board of Health, with the aid of the New Hampshire Tuberculosis Association, to make mass x-ray studies in any or all industries requesting such examination in an attempt to find patients affected with tuberculosis. The Venereal Division is also to be allowed to do the routine blood Wassermann examinations. Patients, after the above check, are to be referred back to their own physicians. After much discussion, it was decided to inquire of other states their experience regarding the cost of such studies and the reactions of the physicians in the states that have held these industrial examinations.

This meeting was then adjourned.

The second meeting was held on September 30, 1941, in the same location and Drs. Burroughs, Vintner, Powers and Smart were present. The above-mentioned program

was discussed and Dr. Metcalf, secretary, was called in to give his advice, which was that the present policy of the New Hampshire Medical Society would, he thought, be against the State Board of Health's taking over such a program. New Hampshire is one of the most highly developed industrial states, having about 142,000 on the employees' compensation roll. It seems to your committee that such an ambitious program of mass x-ray films would entail a large expense, and we are of the opinion that in this time of war upheaval it might be better to await a more thorough investigation by the Committee on Public Health concerning the time and desirability of such a program.

The second important question that came to your committee's attention was that of having the State Board of Health, in collaboration with the Committee on Public Health, formulate certain minimum requirements for first-aid rooms in industries so that there would be some place in the State where such guidance could be found for industries that are now trying to establish their first-aid accommodations. An outline has been drawn up, and your committee recommends that the Medical Society adopt this plan.

Another meeting was held on March 13, 1942, in the Governor's Council Chamber at call of John J. Hallihan, of the Department of Public Welfare, a committee appointed by the Governor to accumulate firsthand knowledge of the tuberculosis situation in New Hampshire, and especially the sanatoriums; two weeks later, your committee inspected the Pembroke Sanatorium, and later was requested to inspect the Glenclyff Sanatorium. This study is incomplete, and no report is possible at present.

Finally, the National Council on Industrial Health requests that the Society send a representative to its fifth annual meeting, and it is the opinion of your committee that, if the New Hampshire Medical Society desires an active and progressive public-health committee, it authorize the sending of such a representative to this meeting.

CHESTER L. SMART, *Chairman*
HARRIS E. POWERS

Dr. Sycamore stated that the Committee on Officers' Reports commended the members of the Committee on Public Health for the vigorous and judicious activities of this new committee. Their decision that further study should be given to the question of mass x-ray and serologic examinations in industrial establishments was approved.

Dr. Sycamore recommended that the House of Delegates approve the collaboration of the Committee on Public Health with the State Board of Health in formulating minimum requirements for first-aid rooms in industries.

In view of the importance of industrial health in the war effort, it was recommended that the committee be authorized to send a representative to the National Council on Industrial Health, the expenses of the representative to be defrayed by the Treasurer.

A motion to adopt this portion of the report was duly seconded and was carried.

Dr. Benjamin P. Burpee then presented the report of the Committee on Maternity and Infancy.

Report of the Committee on Maternity and Infancy

There was a gratifying reduction in the maternal death rate for 1941. For eight years, the committee has studied and analyzed every maternal death reported, making an effort to appraise, so far as possible, the problems relating to causes of death among mothers and infants.

Each year, the committee has made its report to the New Hampshire Medical Society, but in the past five years, including 1942, the report has been printed and distributed widely to physicians, hospital superintendents, and nurses. It is our opinion that the results shown and recommendations made—based on findings in the analysis of each case—have been of definite assistance to many physicians in the conduct of obstetric practice. For the past two years, the committee, through its agent, has corresponded with each physician reporting a maternal death with the view to making such suggestions or rendering such consultation as may be of value. Many physicians have responded with interest and gratitude for the suggestions and recommendations of the committee. During the past year, there was an unusual display of co-operation every physician and hospital being most willing to supply the committee with all possible help and information.

As in the past, the study was conducted by the committee through an agent, the only person knowing the identity of the physician and patient or hospital. That person is the Director of the Division of Maternal and Child Health of the State Board of Health. Each case was studied objectively and thoroughly, the committee endeavoring to analyze the facts and draw conclusions from those facts. In some cases, obviously, no definite conclusions regarding the exact cause of death could be made. This was true chiefly in cases in which no autopsy findings were available. However, the committee endeavored to classify each death.

Prevention of maternal and infant deaths is, of course the prime concern of all. In this analysis, it is encouraging to note that most of the deaths were in the classification of unavoidable and that many were due to accidents of pregnancy.

The study of infant deaths and stillbirths was less thorough because it was impossible to gather complete data on such large numbers of cases. The best that could be done was to appraise the deaths by means of the causes reported. In the report, the deaths are tabulated as to causes, and some conclusions were drawn from such a tabulation.

Stillbirths were analyzed from the data secured from questionnaires sent to physicians reporting stillbirths. Most questionnaires were filled out and returned, but some information is lacking from others. A tabulation of stillbirths as to reported causes follows in the report.

It should be understood at the beginning that the remarks and recommendations of the committee are entirely impersonal and objective, since the committee did not know the identifying information for any case reported.

The record of marked decreases in maternal mortality is of special significance in view of the present emergency and under war conditions. With the possible disruption of family life, changes of large groups of population, housing and sanitary problems resulting from possible crowding in defense areas in the State, the inevitable shortage of medical and nursing personnel in many areas may show serious effects on family life in New Hampshire, as elsewhere, and may cause a rise in maternal and infant mortality. The new low rate of 1.8 per 1000 live births for New Hampshire may therefore serve not only as a measure of past accomplishments but also as a means of pointing to the possibilities in meeting the difficult problems of the future.

This low rate is significant not only in terms of fewer maternal deaths but also in that the birth rate in the State was higher than at any time since 1920. It is the hope of the committee that despite problems and difficulties arising out of the war, physicians and hospitals will not relax their standards of good care, but will in fact press every effort to advance toward better obstetric practice.

During the year, the committee held five meetings.

MATERNAL DEATHS

In 1941, there were 17 maternal deaths. During that year, there were 9616 live births. The rate for maternal mortality was therefore 1.8 per 1000 live births. Each of the 17 deaths was studied and classified according to the *International Classification of Causes of Death* (fifth revision). These deaths were reported for the calendar year ending December 31, 1941. Following an appraisal and scrutiny of each case, the committee reclassified the deaths into categories of causes according to the data received and conclusions drawn from the data, as follows:

CODE NO.	CAUSE OF DEATH	NO. OF DEATHS
140 (c)	Abort on (self induced)	2
140 (d)	Abort in (not self induced)	1
144 (a)	Toxemia of pregnancy with convulsions—death before delivery	2
148 (a)	Toxemia of pregnancy—death after delivery	2
147 (a)	Placenta previa (post partum hemorrhage)	1
146 (c)	Post partum hemorrhage	2
147 (b)	Puerperal sepsis	1
144 (d)	Puerperal embolism	1
149 (a)	Accidents of pregnancy (inversion of uterus)	1
149 (f)	Accidents of pregnancy (malposition cesarean section embolism and so forth)	3
		<hr/> 17

In order of frequency of cause as determined by the careful analysis of each case, the committee reclassified them as follows:

CAUSE OF DEATH	NO. OF DEATHS
Toxemia of pregnancy (all types)	4
Accidents of pregnancy	5
Puerperal embolism	1
Inversion of uterus	1
Transverse position	1
Post partum hemorrhages	3
Placenta previa	1
Retro placenta	1
Cause undetermined	1
All others	3
Cesarean sections	1
Puerperal sepsis	1
	<hr/> 17

Only two cesarean sections were performed in the 1941 series of maternal deaths. One was performed for a good indication, but one was done for what the committee considered no proper indication.

In the series, only three autopsies were performed.

As in the past all cases were further classified into three categories—Group I, those in which the patient was at fault because of refusal of prenatal care, neglect, or self induced abortion and so forth; Group II, those in which the obstetric treatment was inadequate; Group III, those which were apparently unavoidable,—as follows:

CLASSIFICATION	NO. OF DEATHS
Group I	4
Group II	5
Group III	8
	<hr/> 17

The causes of death in Group I, in which the patient was at fault, were as follows:

CAUSE OF DEATH	NO. OF CASES
Induced abortion	3
Toxemia of pregnancy (treatment refused)	1
	<hr/> 4

The causes of death in Group II, in which the obstetric care was inadequate, were as follows:

CAUSE OF DEATH	NO. OF CASES
Post-partum hemorrhage	1
Cesarean section	1
Puerperal septicemia	1
Toxemia	2
	5

The causes of death in Group III, in which the deaths were apparently unavoidable, were as follows:

CAUSE OF DEATH	NO. OF CASES
Inversion of uterus	1
Acute pulmonary edema	1
Pulmonary embolism	1
Puerperal sepsis	1
Post-partum hemorrhage	2
Chronic nephritis	1
Cesarean section (obesity)	1
	8

Some gratifying facts are noted concerning the causes of deaths as classified in the foregoing tables. In the first place, the majority of deaths were undoubtedly accidents of pregnancy. Coming under this group are of course the embolic phenomena, malpositions, inversion of the uterus and adherent placentas. There was less evidence that really poor obstetrics was practiced in the handling of such problems in this series of cases, as compared with past series. The medical profession would like to believe that the increasingly lowered death rate is due to better obstetrics.

Toxemias continued to be proportionately the chief cause of death in New Hampshire. The largest number of deaths were due to accidents of pregnancy. In the United States as a whole, infections were the chief cause of death, causing 41 per cent* of the maternal deaths in 1940 (figures for 1941 for the United States as a whole are not available). As compared to infections, the toxemias caused 25 per cent of maternal deaths in the country as a whole in 1940, and post-partum hemorrhage was the cause of 23 per cent.

Because toxemias still present the greatest problem, the committee believes that recommendations regarding accepted methods of treatment should be reiterated in this report; this follows below.

If accidents occurring in pregnancy, at the time of delivery or in the post-partum period are excluded, the other deaths recorded were for the most part preventable. Induced abortions are surely unnecessary, and should be vehemently stopped. It does present a real problem in the efforts of the profession to reduce maternal mortality. The medical profession should not rest until every preventable cause of maternal death is reduced to an absolute minimum.

In the 1941 series, 15 patients were delivered in hospitals, and 2 in the home. The following data on urban and rural residency are also of interest:

COUNTY	URBAN CASES	RURAL CASES	TOTAL CASES
Belknap	0	0	0
Carroll	0	1	1
Cheshire	4	2	6
Coos	1	1	2
Grafton	2	0	2
Hillsborough	4	0	4
Merrimack	0	0	0
Rockingham	1	0	1
Strafford	1	0	1
Sullivan	0	0	0
	13	4	17

To illustrate the trend in maternal mortality statistics, the following data are presented:

YEAR	NO. OF DEATHS	MATERNAL MORTALITY RATE PER 1000 LIVE BIRTHS
1930		62
1932		54
1933		63
1934		54
1935	46	61
1936	37	48
1937	34	43
1938	24	38
1939	25	31
1940	24	28
1941	17	1.8

Data are available from the United States Bureau of the Census for maternal deaths for 1940. It is of interest that, in a comparison of percentage decrease in maternal deaths for the period of 1931-35 with 1936-40, New Hampshire had a 37.5 per cent decrease in the latter period. The maternal death rate in 1931-35 was 6.27 per 1000 live births, as compared with 3.92 in 1936-40. With the present low maternal death rate of 1.8 per 1000 live births, this percentage decrease is most gratifying. New Hampshire is grouped with the states that show a percentage decrease of 35 per cent or more for the period.

These census figures further indicate that for 1940, 11 per cent of the total maternal deaths were due to abortions and 7 per cent were due to ectopic gestation; 26 per cent of patients died before delivery, and 56 per cent died during or after delivery. It seems that many of the 56 per cent of deaths occurring during or after delivery could have been prevented. Many of the deaths in this period were due to infection.

In next year's report, it may be possible to include figures based on these problems for the 1941 deaths. Such figures have not as yet been analyzed.

The increasing and apparent downward trend in maternal mortality rates is significant statistically, and it can be inferred that better obstetric care, more adequate hospital facilities, better quality of nursing care and improved methods of treatment are most presumably responsible. These efforts must continue with all the vigor of the profession and agencies engaged in educational health work for the civilian population.

One outstanding improvement should be commented on. This is a matter of hospital records. It was definitely apparent that better records, more complete information, more laboratory findings and so forth were available in hospital cases. Physicians are still found to keep very inadequate or no records. Physicians should realize that good records are not only indispensable in the intelligent care of a patient but also a protection to the physician in the event of legal procedures.

As reported for last year, hospital facilities have improved markedly. Several hospitals have built new wings for maternity and infant care; better fire protection was provided, and New Hampshire has a new well-equipped hospital to add to its facilities. On the whole, the care of maternity patients has shown an encouraging improvement. The efforts of public-health agencies regarding such improvement are well worth mentioning.

In most cases, more prenatal care was sought by patients and provided for by the medical profession.

RECOMMENDATIONS AND COMMENTS

Recommendations of the committee and comments on problems arising have been considered of value to physicians reporting their numerous problems and to those who are aware of difficulties connected with the puerperium. This year, the recommendations are based on

*Figures obtained from United States Bureau of the Census.

actual case studies analyzed from data collected and presented herein by way of illustration. The comments arose from the objective conclusions arising out of the study. The more important recommendations of past years are also included for emphasis by repetition.

The committee recommends that no attempt be made at the delivery of a central placenta previa from below in either a primipara or a multipara.

It is recommended that in cases in which an adherent placenta occurs, 1 cc pituitary extract be given at two hour intervals and accompanied by the Crede maneuver only at the same time that pituitary extract is given. This should be tried before any attempt at manual removal is made. Manual removal is unjustifiable under 12 hours unless there is excessive and uncontrollable bleeding. The Crede maneuver, moreover, should be performed with care and skill, so as to avoid trauma of the uterus.

The committee disapproves of the use of vaginal or cervical packs. The danger of masking the bleeding into the uterus and of subsequent infection is feared by such methods.

Cesarean sections should not be performed without competent consultation and without absolute indication. The committee believes especially that a section should not be done when the membranes have been ruptured for twenty-four hours.

Versions should not be done unless the patient is deeply anesthetized.

The committee believes that most occiput posterior positions will right themselves or deliver spontaneously if enough time is allowed and watchful waiting considered.

The committee recommends that autopsies be performed on every maternal death.

In addition to recommendations based on the 1941 study, the committee reiterates that physicians should keep better and more useful records, that hospitals require consultations for operative deliveries, and that when hospital facilities are available, every possible effort be made in the diagnosis and intelligent treatment of toxemias, anemias, malpositions, infections and other complications of pregnancy.

INFANT MORTALITY

The following is a tabulation of causes of deaths in infants as reported on the death certificates. These are divided into periods as to when the deaths occurred in relation to birth for those under one year of age.

CAUSE OF DEATH	NO. OF DEATHS
Deaths occurring on or before the first day of life	
Prematurity	98
Congenital deformity	71
Asphyxia	8
Other	6
Cerebral hemorrhage	3
Unknown	3
Birth injury	7
Hemorrhage of newborn	1
	<hr/> 151
Deaths occurring in the first month exclusive of the first day	
Prematurity	16
Congenital deformity	16
Cerebral hemorrhage	9
Asphyxia	3
Atelectasis	4
Intestinal obstruction	2
Gastroenteritis	2
Pneumonia	8
Other	2
Malnutrition	2
Syphilis	1
	<hr/> 70

Deaths occurring from the second to the twelfth month inclusive	
Pneumonia	36
Other	12
Gastroenteritis	13
Malnutrition	10
Suffocation	9
Congenital malformations	8
Whooping cough	5
Unknown	4
Septicemia	1
	<hr/> 98

The total number of infants who died in 1941 under one year of age is 319, in 1940, there were 274 deaths. This is a challenging increase. The largest single cause of death is still given as prematurity, and it is interesting that as many as 9 infants died of suffocation from carelessness. Many of the congenital deformities were due to congenital heart disease.

The infant death rate for 1941 is 33 per 1000 live births.

The infant mortality rates per 1000 live births by years are as follows:

YEAR	RATE
1935	54
1936	47
1937	48
1938	48
1939	45
1940	32
1941	33

STILLBIRTHS

Two hundred and eighty-one stillbirths were reported in 1941. Questionnaires were sent to all physicians reporting stillbirths, and answers were received for 182 cases.

The causes of stillbirths were tabulated as follows.

CAUSE	NO. OF CASES
Prematurity	24
Congenital deformity	34
Instrumental delivery	13
Toxemia	13
Cerebral hemorrhage	6
Deformities of placenta or cord	50
Unknown	20
Other	16
	<hr/> 187

The number of stillborn infants reported from year to year varies markedly. Many of the stillbirths this year were reported on the questionnaires as due to abnormalities of the placenta or accidents caused by a twisting of the cord about the baby's neck. The committee does not believe that such conditions constitute real causes for stillbirths. A large number of infants died without any apparent or proved cause, even after autopsy findings were recorded.

Stillbirths for the past few years were as follows:

YEAR	NO. OF CASES
1937	181
1938	242
1939	211
1940	187
1941	281

No conclusions can be drawn concerning this variation.

The committee wishes to express its gratitude and satisfaction for the excellent record shown in New Hampshire in 1941 concerning reduced maternal mortality. Appreciation is expressed for the co-operation of physicians and hospitals in making this report possible, and for the encouraging improvements in hospital facilities and better obstetric practices. As in the past, thanks should be given for the co-operation of the Division of Maternal and Child Health of the State Board of Health, whose facilities and personnel were used by the committee in making this study and in preparing this report.

ROBERT O. BLOOD, *Chairman*
BENJAMIN P. BURPEE
MARION FAIRFIELD

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28311

PRESENTATION OF CASE

First admission. A fifty-eight-year-old Polish housewife was admitted to the hospital because of weakness and shortness of breath of three years' duration.

Seven years before entry, the patient fractured her right humerus while pushing away a heavy object. In the next few years, she began to have various body aches, centering in the lower part of the back, shoulders, arms and legs. These aches were not related to posture, fatigue or exertion. There was insidious onset of slight weakness and shortness of breath on exertion. Two years before entry, the patient slipped while scrubbing a floor, and sustained another fracture through the upper right humerus. At that time, roentgenograms taken by a physician showed extensive bone destruction of the proximal half of the humerus by a trabeculated cystic lesion, and similar destructive processes in the right seventh rib, the proximal end of the left femur, and the right and the left ilium. There was also an old fracture of the right clavicle. The patient was given roentgen-ray therapy in nine doses over a period of two weeks in total amounts of 1600 r to the left femur, 1800 r to the right humerus, and 3500 r to the right and left parathyroid regions (half to each side); there was tanning of the skin. Roentgenograms taken nineteen months before entry showed new-bone formation in the areas of destruction noted earlier in the right shoulder, but no change in the lesions in the pelvis. Thirteen months before entry, an additional treatment of 1200 r was given to the parathyroid regions. Fourteen months before entry, blood examinations by another physician showed a red-cell count of 2,600,000 with 55 per cent hemoglobin, and a white-cell count of 3300. The serum calcium was 11 mg. and the phosphorus 3.5 mg. per 100 cc., and the phosphatase was 1.5 Bodansky units. The patient was given large doses of dicalcium phosphate and vitamin D, with progressive relief from body aches. Courses of liver-extract injections, daily doses of ferrous sulfate and three blood transfusions were also given, but there was only transitory improvement in the blood picture. In the two years preceding entry, the patient had several attacks of

severe sharp pain in the lumbar region, not relieved by mustard plasters. She had no chills, fever or hematuria in association with these attacks; however, about a year before entry, there was blood in the urine on several occasions when there was no back pain. She never passed gravel. There was no polydipsia.

The past and family histories were irrelevant. The menses were normal until the menopause ten years before entry.

On admission, the patient appeared elderly and obese. The mouth was edentulous, with pale mucous membranes. There were palpable thickenings of the midportion of the right clavicle and upper right humerus. A single small node was palpable in the right axilla. The heart and lungs seemed normal. The tip of the spleen was easily felt beneath the costal margin in the anterior axillary line. It was firm and not tender. The abdomen and extremities were otherwise normal. Pelvic examination showed a large laceration of the cervix, with surrounding erosion.

The blood pressure was 150 systolic, 90 diastolic. The temperature was 100°F., the pulse 92, and the respirations 20.

Examination of the blood showed a red-cell count of 2,130,000 with 7.4 gm. hemoglobin and 2.8 per cent reticulocytes. The red cells showed stippling and polychromasia. The white-cell count was 2200 with 69 per cent polymorphonuclears, 26 per cent lymphocytes and 3 per cent monocytes. The blood Hinton reaction was negative. The formol-gel test was negative. The blood calcium was 14 mg. and the phosphorus 1.5 mg. per 100 cc., the phosphatase 5.4 Bodansky units, the serum albumin 4.7 gm., the globulin 2.1 mg., and the non-protein nitrogen 26 mg. per 100 cc. The cholesterol was 159 mg. per 100 cc. The carbon dioxide combining power was 23.1 milliequiv. and the chlorides 107.2 milliequiv. per liter. The van den Bergh reaction was normal. The urine showed a ++++ Sulkowitch reaction (calcium phosphate in urine), but contained no albumin. There were occasional red and white cells in the sediment. The phenol-sulfonephthalein excretion was 50 per cent in two hours. The urine was positive for 10 mouse units of follicle-stimulating hormone per 100 cc. The excretion of 17-ketosteroids was 3.3 mg. per 24 hours. An electrocardiogram was normal.

Roentgenograms of the skeleton showed extensive decalcification, with thickening of the cortex. There was some new-bone formation in the medial portion of the right ilium, and multiple cysts were present in the upper end of the left femur and in both ilia (Fig. 1). The ribs and humeri also contained cysts. The structure of the skull was markedly altered, with indistinctness of the diploë

and blood vessels. There were platybasia and wedge appearance of the dorsal vertebrae. In roentgenograms of the chest, the heart appeared normal. The lung fields showed only apical scars. A rounded mass, 7 cm. in anteroposterior diameter and 6.5

shoulders, with weakness and a sense of heaviness in the chest. Four weeks before readmission, a persistent cold was contracted. Pains then reappeared in the right arm at the site of the old injury, and there was some cramping in the legs.

FIGURE 1.

cm. in lateral diameter, lay in the mediastinum below the arch of the aorta and just beneath the sternum. The esophagus showed a traction diverticulum in its middle third. A flat film of the abdomen showed kidney shadows slightly smaller than usual. Two small areas of calcification lay in the region of the lower pole of the left kidney. A laminated gallstone-like structure lay in the liver region. The spleen appeared enlarged. An intravenous pyelogram showed prompt excretion of dye. The pelvis and calyces were relatively small, with the aforementioned stone on the left, but were otherwise negative.

The patient was given 1200 r to the anterior mediastinal field, and a similar amount to the posterior mediastinal field. Repeated chemical studies of the blood showed no essential change after the irradiation. The patient was given a blood transfusion and discharged to the Out Patient Clinic.

Second admission (three months later). The patient continued fairly well, and was able to do housework. There was some pain in the back and

There were several slight nosebleeds. The appetite was only fair.

On readmission, physical examination was essentially as before. An area of dullness over the sternum at about the second interspace extended to the left about 2 cm. Laboratory data were essentially as before. Throat, blood and urine cultures were negative. The corrected blood sedimentation rate was 0.9 mm. per minute.

A roentgenogram of the chest showed no essential change in the mass in the mediastinum.

On the twentieth hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. JOSEPH C. AUB: We have here the story of a Polish woman, past the menopause, with progressive fatigue, marked bone and muscle pains, anemia, a large spleen and too few white cells. These findings had lasted for years. She had known that she had bone lesions for two years, and large doses of x-ray therapy did nothing to them. The duration and course of the difficulty

practically rule out the diagnosis of myeloma.

The low 17-ketosteroid excretion puzzles me. It should be higher after the menopause.

DR. FULLER ALBRIGHT: That is all right for a debilitated person.

DR. AUB: Yes, but a little low.

DR. ALBRIGHT: Low for a normal person.

DR. AUB: These x-ray films are fascinating. I should like to ask Dr. Schatzki about the skull and about the feet. What does "platybasia" mean?

DR. RICHARD SCHATZKI: In platybasia, the cervical spine is pushed into the floor of the posterior fossa, like a piston. This occurs during early development.

DR. AUB: Should it help me in the diagnosis?

DR. SCHATZKI: I do not believe so. Whether it may develop later in life, I do not know.

DR. ALBRIGHT: Yes; it does. Any decalcifying process will do it.

DR. AUB: Is that moth-eaten appearance more than normal, according to your technic?

DR. SCHATZKI: Yes.

DR. AUB: What about the toes?

DR. SCHATZKI: I am wondering about them myself. I should say that although the cortex of the skull is definitely thickened, the cortex of the toes is by no means thickened, but thin, and they are decalcified. I should say that the feet show merely marked decalcification.

DR. AUB: Are these trabeculae abnormal?

DR. SCHATZKI: There may be tiny cysts in one of the toes, but actually all you see in the feet can be explained by decalcification.

DR. AUB: Is this traction of the esophagus just where the tumor in the chest is?

DR. SCHATZKI: No; I should say that was a traction diverticulum of the esophagus—it is of no clinical importance.

DR. AUB: They do not fit together—the mass and the traction diverticulum in the esophagus?

DR. SCHATZKI: The mass is in the anterior mediastinum in front of the arch. It has nothing to do with the esophagus. It is far away from the esophagus.

DR. AUB: I think this is a very puzzling case. Of course, the obvious diagnosis is parathyroid tumor. The patient had a high calcium, low phosphorus and a normal phosphatase level in the blood. She had kidney stones, and was passing bloody urine. All these things are typical of hyperparathyroidism, but I do not want to make the diagnosis because she also had a large spleen and something wrong with the blood. There are several red herrings in this case, such as the mass in the chest. It may have been a thymoma, but so far as I know, they never give a syndrome like this. It may have been thyroid or parathyroid tu-

mor. We assume it was pushing the esophagus over, and I do not believe a parathyroid tumor would have done that. It may have been Hodgkin's disease or a tumor of the lymphoma series, but the picture does not correspond to generalized reticulum-cell sarcoma because it lasted too long. This bone lesion could be a lipoid dystrophy like Gaucher's disease. May I ask whether there were yellow spots on the scleras, especially toward the inner canthi.

DR. HARRY F. KLINEFELTER: No, there were no pingueculae.

DR. AUB: The patient was fifty-seven years old. Gaucher's disease would give her many of the things she had, but I have never heard of its producing a high blood calcium and a low blood phosphorus. It would give bone lesions. It could give a moth-eaten appearance like the x-ray picture in the phalanges and the thickened bones of the femurs. It would produce the large spleen, the anemia and the low white-cell count, and could explain all these things and bring the picture together, except for the high blood calcium and low phosphorus. On the whole, I think one of the xanthomas—of which Gaucher's disease would be the likeliest, because of the age—would explain the low cholesterol, and everything else would go with it; I do not believe this woman had cancer. I am quite sure that she did not have multiple myeloma. I do not believe she had lymphoma, and I am unwilling to make a diagnosis of hyperparathyroidism. I do not believe that Gaucher's disease is a good diagnosis, but it is the diagnosis that explains most of the findings and I am therefore willing to make it.

DR. TRACY B. MALLORY: Dr. Schatzki, do you want to comment on the possibility of Gaucher's disease as an explanation of the bone lesions?

DR. SCHATZKI: The spleens in Gaucher's disease are usually larger than the spleen in this case.

DR. AUB: Yes; much larger, and there ought to be little xanthomas in the eyes, which this patient apparently did not have.

DR. SCHATZKI: From the roentgenologic point of view, this is not Gaucher's disease. Cases with Gaucher's disease do not show real cysts.

DR. ALBRIGHT: I think they do not have cysts and are very radiosensitive.

DR. AUB: In Gaucher's disease? No.

DR. ALBRIGHT: Yes.

DR. MALLORY: The authorities seem to disagree.

DR. SCHATZKI: Gaucher's disease does not produce decalcification of the feet.

DR. AUB: No, it does not.

DR. SCHATZKI: One thing is wrong with the description in the abstract so far as the x-ray film is concerned: except for the skull there is no thick-

ening of the cortex of the bones. The cortex of the femur is normal, and that of the humeri, radii and ulnae is definitely thin.

DR AUB: The patient had an elevated calcium output. Should you make a diagnosis of hyperparathyroidism on that femur?

DR. SCHATZKI: I should not rule it out by any means. The femur alone shows the cysts. There are cysts and a thin moth-eaten appearance. I think that is all right.

DR AUB: I think it may be xanthoma. However, if you want to ask me what operation should be done, I should operate and take a biopsy of the bone.

DR EDWARD D. CHURCHILL: You are not advising a splenectomy or mediastinal exploration or a neck-cervical exploration for parathyroidism?

DR AUB: I strongly suspect that you did look at the lesion in the chest, but I should have had a biopsy of the bone first. Did you do a biopsy?

DR OLIVER COPE: Yes.

DR AUB: Of what?

DR COPE: A biopsy of the ilium.

CLINICAL DIAGNOSIS

Hyperparathyroidism

DR AUB'S DIAGNOSIS

Grucher's disease

ANATOMICAL DIAGNOSES

Osteitis fibrosa cystica

Adenoma of the parathyroid

Neurofibroma of mediastinum

PATHOLOGICAL DISCUSSION

DR MALLORY: The wall of one of the cystic cavities in the ilium was chiseled off. The cyst contained material resembling a benign giant cell tumor, and its bony margins were characteristic of osteitis fibrosa.

DR AUB: Then, it is obvious that the patient must have had a parathyroid tumor. I do not understand why you x-rayed this woman so hard.

DR MALLORY: I suggest we defer discussion on that point until Dr Cope has told us about the second operation.

DR COPE: We had an amusing time arguing about this diagnosis because none of us was exactly right. Dr Albright and I thought the tumor mass seen by x-ray study must be parathyroid. Dr J. H. Means was on service and thought it was not, arguing that it was too low and too large and that it must be thyroid tissue in the mediastinum. But we have seen one parathyroid adenoma in our series that was as large as this. As a mat-

ter of fact, the adenoma from the first case we had weighed 53 gm., and one other patient had one almost as large. Chemically, the patient under discussion had an endocrine disease,—hyperfunction of the parathyroid hormone,—and when a tumor mass is demonstrated on physical or x-ray examination, the burden of proof is on him who says that the tumor is not the cause of the disease. X-ray treatment was decided on because this seemed the case par excellence to prove the inefficiency of such therapy. Not knowing exactly where the tumor was in the other 5 patients who had received such treatment, we were never sure that the irradiation had reached the tumor. I was therefore in full sympathy with having this tumor irradiated.

We divided the sternum at operation down the midline, and as I put my finger in to go underneath and push the pleura away from the under surface of the sternum, I felt ahead of my finger a soft, small tumor. It was not in the place of the large tumor, but higher up. By great good fortune for the patient, the actual parathyroid tumor

FIGURE 2

was also in the anterior mediastinum. Its shadow in the x-ray film is probably this one just above the larger tumor. This is a photograph of the two tumors removed at operation, placed on a drawing of the chest and neck (Fig 2). The parathyroid

tumor was within the thymic capsule, and this lighter colored tissue attached to it is a piece of the normal thymus gland. This patient is one of the roughly 10 per cent of people with hyperparathyroidism whose tumor lies in the anterior mediastinum instead of in the neck. It was good fortune because we did not explore her neck first, and if the tumor had not been in the mediastinum we should have had to explore her neck at a second operation.

We had an amusing time with the pathologists too. I had already taken out the parathyroid gland,—I thought it was parathyroid,—but it was quite green; Dr. Castleman looked at it and said, "Well, I am not sure of that." Dr. Churchill, on the other hand, was quite sure it was parathyroid. We were all agreed about the larger tumor, which was hard and firm and looked like a thyroid tumor.

DR. SCHATZKI: Dr. Albright prompted us to treat the patient because the literature contains numerous reports of beneficial results from treating parathyroid tumors with x-rays. He thought we could see the tumor, and if it shrank we should have definite proof that it was radiosensitive. It did not change in size, however.

DR. ALBRIGHT: I wanted to prove the fallacy of x-ray treatment once and for all.

DR. MALLORY: Microscopic sections of the tumors eventually proved that the smaller mass was a parathyroid adenoma and the larger one a mediastinal neurofibroma. Its presence must be regarded as pure coincidence, and it obviously had nothing to do with any of the symptomatology.

DR. COPE: The color interested me. The parathyroid tumor was brown when I first exposed it within the thymic capsule, but I divided its arterial blood supply. Ordinarily, when we excise a parathyroid tumor, we take the entire pedicle out with one snap, so that the blood is retained within the adenoma. This time, the arterial supply came from above, and the main venous return was from below. I divided the arterial supply first, and all the blood had drained before the veins were severed. With the loss of blood, the tumor turned a curious green. I realized on looking back that I had seen this happen before but had never made proper note of it.

DR. WILLIAM B. BREED: We still have not settled the low phosphatase.

DR. AUB: Did the phosphatase go up?

DR. COPE: Two months after operation, it had gone up. We have not seen the patient since April 18. Immediately after operation she showed the expected changes. The calcium came down promptly. The phosphorus did not go lower, but started up the first week after operation. Had

there been any amount of osteoblastic tissue that should have been associated with a high phosphatase level, we should have expected the phosphorus to go down rather than up in the initial postoperative period.

DR. AUB: What about the large spleen?

DR. MALLORY: It could have been hematopoietic. After all, the patient had a considerable portion of bone marrow replaced by fibrous tissue.

DR. AUB: That is uncommon with leukopenia, is it not?

DR. ALBRIGHT: We had another case with equally bad anemia without a large spleen.

CASE 28312

PRESENTATION OF CASE

A twelve-year-old boy was admitted to the hospital because of repeated fractures of the arm.

When a baby, the patient broke his right wrist. Four years before entry, and again two years before entry, he fractured his left arm. Two weeks before entry, the left arm was broken for a third time, in a fall against a curb while the patient was walking. The roentgenogram taken the day after the accident at another hospital showed a fracture of the humerus, and the patient was transferred to this hospital for treatment.

Examination showed a well-nourished and well-developed boy, with normal chest and abdomen. The arms were of equal length, without local swelling, heat or roughness. Tenderness was noted over the medial epicondyle and upper third of the shaft of the left humerus.

The temperature, pulse and respirations were normal.

Examination of the blood showed a white-cell count of 7300 with 70 per cent polymorphonuclears, 20 per cent lymphocytes, 8 per cent monocytes and 2 per cent eosinophils. The blood Hinton reaction was negative. The serum calcium was 11.7 mg., the phosphorus 4.6 mg. and the phosphatase 7.2 Bodansky units per 100 cc.

A roentgenogram of the left arm showed absence of normal trabeculation of the upper two thirds of the humerus, and thinning of the cortex of the upper quarter (Fig. 1). The medullary cavity was crossed by irregular scattered calcified trabeculae giving the pattern of irregular cysts. There was a fracture of the cortex of the medial aspect of the humerus about 1 cm. below the upper epiphyseal line, apparently involving the wall of a cyst, with a fragment of cortex lying transversely across the bone. The upper humerus seemed questionably expanded. No definite soft-tissue mass was visible. The process did not cross the epiphyseal line.

Roentgenograms of the right arm, right thigh and left forearm showed no abnormalities

On the tenth hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR ERNEST M. DALAND: We are dealing here with a boy of twelve who had three fractures through the same bone, and this last fracture was apparently due to a very trivial blow. It suggests

FIGURE 1

an underlying pathologic condition of the humerus. We must consider three things: simple bone cyst, giant-cell tumor, and a cyst from a generalized process such as osteitis fibrosa cystica, in which there are apt to be many cysts on an underlying parathyroid basis.

I called attention to the fact that there seemed to be no bowing, and in a cyst of the parathyroid type, osteitis fibrosa cystica, there is quite likely to be deformity of the bone and bowing. It is suggested here definitely that there has been a fracture three times through this same cyst, and yet we still have a normal contour of the arm. In review-

ing the x ray films, it is evident that other bones have been examined to rule out the possibility of a generalized fibrous cystica disease. These were reported to be normal and seem to be normal. The serum calcium and phosphorus are high normals,—about what one would expect in a boy of twelve. The phosphatase is normal for a child. I believe, on these grounds, we can rule out osteitis fibrosa cystica, so that the differential diagnosis lies between bone cyst and giant-cell tumor.

The one lesion lies in the upper end of the shaft of the humerus. The note has been made that the condition does not cross the epiphyseal line. That is quite important because a giant cell tumor at the end of the bone will cross the epiphyseal line, extend all the way to the cartilage of the joint but not cross the joint, destroying everything up to the cartilage. This boy, however, showed a process that stopped exactly at the epiphyseal line. The typical giant-cell tumor is, moreover, an expansile type of tumor, so that the tumor itself is roughly spherical. It would not tend to spread down the shaft so far as this has without widening to a greater degree the bone at the upper end of the shaft. Another characteristic of a giant-cell tumor is that at the lower margin where it tends to go down into the shaft, a saucerlike depression is seen in the films and is also easily demonstrable on the operating table. That is quite typical, and I do not see anything suggesting it here. Other types of tumor involving the medulla tend to diffuse out and disappear gradually down into the medulla. I think this is more suggestive of bone cyst because of its lack of great widening, the lack of spherical tendency and the failure to cross the epiphyseal line. The patient had a trivial fracture, which brought him to the hospital. It is quite typical of patients with bone cyst that a fracture first calls it to their attention. There is a tendency for some of these bone cysts to heal spontaneously, once fractured. This boy had two opportunities, apparently, for spontaneous healing after fracture, but the tumor still persisted. If healing does not occur spontaneously, or as the result of operation, there is a tendency toward extension and further cystic degeneration.

My opinion is that this was simple bone cyst, benign, limited to the one bone and with a fracture. The usual method of handling these cases in this hospital is to open into the cyst and curette out the contents and then fill up the cavity with bone chips or osteoperiosteal grafts. Ordinarily, they heal and give satisfactory regression.

DR LAURENCE L. ROBBINS: I think the description of these x ray films is adequate. The appearance is more that of a cystic lesion than of a giant-

cell tumor. It has sometimes been said, and particularly stressed by Dr. M. C. Sosman, that giant-cell tumor never appears until after an epiphyseal line is closed and that it always involves the end of a bone. Atypical cases, which have been called giant-cell tumors on histologic examination, have not crossed the epiphyseal line. This, however, is a fairly characteristic picture of a cystic lesion of a bone.

DR. CHANNING C. SIMMONS: Did the skin in this case show any evidence of pigmented areas?

DR. TRACY B. MALLORY: No.

Have you anything to add, Dr. Smith-Petersen?

DR. MARIUS N. SMITH-PETERSEN: No, except that I am surprised to hear Dr. Daland mention the possibility of giant-cell tumor in a boy of twelve.

DR. DALAND: *Geschickter** has reported several at this age.

DR. SMITH-PETERSEN: About how many turned out to be cysts? Have you seen many at twelve, Dr. Simmons?

DR. SIMMONS: I have seen one case of epiphyseal chondromatous giant-cell tumor. That one crossed the epiphyseal line in a child of thirteen, as I remember.

DR. MALLORY: What about the relative frequency of spontaneous pain in bone cyst as against giant-cell tumor?

DR. SMITH-PETERSEN: I do not believe there would be any difference.

CLINICAL DIAGNOSIS

Bone cyst, left humerus.

*Geschickter, C. F., and Copeland, M. M. *Tumors of Bone (Including the Jaws and Joints)*. Second edition. 832 pp. New York: American Journal of Cancer, 1936.

DR. DALAND'S DIAGNOSIS

Bone cyst (benign).

ANATOMICAL DIAGNOSIS

Bone cyst, left humerus.

PATHOLOGICAL DISCUSSION

DR. MALLORY: This patient was operated on, and a cyst found. The pathologic picture was complicated by extensive hemorrhage, a good deal of it quite fresh and probably secondary to the pathologic fracture. The material curetted out consisted of edematous fibrous tissue, with fresh and old blood in it. No giant cells were found, and nothing that would suggest giant-cell tumor from a histologic point of view.

Would you care to say anything about treatment?

DR. SMITH-PETERSEN: No, except that frequently a little part of the cyst remains and keeps on growing. I think one is apt to be a little too optimistic about the results of packing in bone chips.

DR. DALAND: Was the appearance of this mass that was curetted different from giant-cell tumor? Grossly, could you tell the difference?

DR. MALLORY: I am not at all sure that I could. The cavity was quite well filled with semisolid, deeply blood-stained material. It was not a frankly cystic cavity, but I think the hemorrhage and the complication of fracture were partly responsible for that.

DR. DALAND: Was this found to be one large cystic cavity at operation?

DR. MALLORY: Yes, so far as the operator could make out.

MASSACHUSETTS MEDICAL SERVICE

EVERY licensed physician in Massachusetts will receive by mail this week a brochure describing in detail the methods of operation of the Massachusetts Medical Service, the state wide system for prepaid budgeting of medical care sponsored by the Massachusetts Medical Society. This corporation, popularly called the BLUE SHIELD, will offer protection to employees and their families against the financial burdens of severe illness. As many physicians know, it is the fruit of more than three years' study by a special committee appointed by the Society and is based on the opinions of the best thinking medical men throughout the country. It is, in effect, the physicians' own answer to the grave social problem confronting the Nation

of how best to provide adequate distribution of medical care, and those who have studied the problem believe that this plan is far sounder than the schemes that have been and are being advanced by governmental, state and consumer-co-operative groups.

The present contract will offer hospital surgery, obstetrics and diagnostic x-ray services. It is the initial step in the development of a complete medical service and is limited in scope only because the public is not yet ready for a full coverage contract. The limitations of the contract, however, do not exclude any physician from participation, and every doctor is urged to participate from the outset of the plan, which will next develop a contract covering all hospital expenses and, finally, one including medical expenses in hospital, home and office.

The Blue Shield is an actuality; its charter has been granted, its capital funds have been provided by the Massachusetts Medical Society, and its offices are open at 230 Congress Street, Boston. It has joined forces with the Blue Cross and will reap the benefits of the hospital plan's wide backing by industrial and business leaders, as well as the confidence of its more than 400,000 subscribers. The Blue Cross will take over the administrative functions and the enrollment of subscribers for the Blue Shield, but each will act as an independent organization, with the allocation of costs subject to the approval of the State Commissioner of Insurance. This arrangement will save duplication of effort, needless expenditure of funds and serious loss of time.

Field representatives will begin calling on physicians this week, immediately after the mailing of the Blue Shield brochure. Obviously, they cannot interview the more than 7000 registered physicians in Massachusetts, and it is hoped that the brochure will explain all the details of the plan so amply that many physicians will sign the contracts without having been interviewed and will return them at once to headquarters.

The tempo of the times is swift, and the social problem that the new plan can solve is pressing. The Blue Shield has announced that it will be

ready for the public, with the Massachusetts medical profession solidly behind it, shortly after Labor Day. This goal can be achieved only if *every* physician in the State makes it his individual responsibility.

INDUSTRIAL MEDICINE FOR PRACTITIONERS

THE precipitous current events in the world at large can leave no lingering doubts in the mind of any group or individual that now is the time to "pick up the ball and run": one should not postpone adjustments, inconveniences or sacrifices that will contribute to the preservation of the Nation. The medical profession is fortunately placed in being able to contribute to this purpose in many ways: the younger members of the profession are being called to posts of active military duty; many of the older physicians are returning to hospital and teaching staffs and even to private practice; and the middle-aged doctors—most of whom served in the last war—are experiencing no difficulty in finding opportunities to apply themselves and their skills in all sorts of civilian activities.

Although the members of this middle-aged group are, or soon will be, carrying the heaviest practical burden, they are probably more goaded than other physicians by their inability to participate in a more direct way than that permitted by their physiologic limitations. They are partially compensated by serving on various boards and committees and by more extended tours of practice, but as they find their medical journals devoting more and more space to the military aspects of medicine and surgery, and when they glance at the headlines of the daily press, they must be frequently plagued by their inability to express themselves more concretely in the war effort.

How can these middle-aged physicians remaining in civilian practice intensify their influence in the total drive against impending disaster? A partial answer for many, and a complete answer for some, may be found in the cultivation of an interest in industrial health in their towns and

neighborhoods. In Massachusetts, three quarters of the industrial workers are employed by small companies. To date, the development of modern industrial medicine has been chiefly confined to the large plants, with their more serious problems and greater resources; as a result, its application to each and all the hundreds of little shops has been overlooked. Yet many of these small factories are now open night and day, thus exposing thousands of workers to hazards against which they might be very easily protected.

Who is going to cast a preventive eye on this widely dispersed problem? Who could do it more effectively than the local physician—the doctor who is asked to remove the foreign bodies, to suture the lacerations, to soothe the irritated skins, to x-ray the broken bones, to assuage the gastrointestinal disturbances and to calm the paranoid grievances of the more unstable but nevertheless productive workers? Here is a great untilled field—untilled because it does not lend itself to the wholesale methods that have brought such good results in the larger plants. The acreage is subdivided into hundreds of small plots, each of which must be worked by the hand of the local doctor, who can make himself see the possibilities of industrial-accident prevention as plainly as he saw those of diphtheria prevention twenty years ago.

If the local physician needs assistance in this matter, it is already within his reach. For a beginning, he may heed the announcement of the Committee on Industrial Health in this issue of the *Journal*. In the pamphlet there referred to, he will find a series of references and agencies that can help him. He may consult the *Manual of Industrial Health*, which will soon be issued by the Council on Industrial Health of the American Medical Association. He may subscribe to *Industrial Medicine*, the official monthly publication of the American Association of Industrial Physicians and Surgeons. Primarily, however, he should visit the plant or plants where he is occasionally called to serve, and he should do so with a trained, critical and inquisitive eye. Only in this way can he

accomplish results, and only in this way can he attract the attention of employers and the more intelligent employees to these results.

The alignment of all plants and factories, regardless of their size, to the modern practice of industrial medicine and hygiene would be a stupendous contribution to the war effort; and its accomplishment is clearly the opportunity of the middle-aged physician who remains in civilian practice.

OBITUARY

WALTER JOSEPH LAMARCHE

1859-1942

The death of Dr. Walter J. LaMarche on May 30, 1942, after a short illness calls for recognition. He was in his eighty-third year and had practiced medicine in Cambridge for fifty years, where his kindly manner and personal interest in his patients earned him their respect, friendliness and loyalty. His interest and his care were as sincere and genuine in his visits to the hopeless and incurable at the Holy Ghost Hospital for Incurables, which he served many years, as it was with his private patients, who offered a more hopeful prognosis and gave more inspiration—a test that many of us find hard to meet. He was for several years identified with the Orthopedic Department of the Massachusetts General Hospital and faithfully gave to it his time and attention.

He had been a pupil of Pasteur in Paris; his command of the French language helped him to a personal touch with the great scientist, and at times with his friends, almost always after a little urging, he would reminisce thereof. Dr. LaMarche was popular among the profession and invariably courteous to his confreres. He will be greatly missed by his many patients, of both short and long tenure, who benefited by his constant kindness and understanding.

Requiescat in pace.

A. W. D.

MEDICAL EPONYM

PROFETA'S LAW

This law was enunciated by Dr. Giuseppe Profeta (1840-1910), of Palermo, in an article, "Sulla Sifilide per Allattamento [Syphilis from Nursing]," that appeared in *Lo Sperimentale* (IV series 15: 328-338 and 339-418, 1865). A portion of the translation follows:

Thus, the healthy child born of a syphilitic mother may with impunity take the breast of its own mother or that of a syphilitic nurse, and neither the milk nor the presence of infectious lesions on the breast of the mother or the wet nurse is capable of transmitting the disease.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON INDUSTRIAL HEALTH

The Committee on Industrial Health calls the attention of the fellows of the Society to a pamphlet, *Manual on Industrial Health for Defense*, which has been prepared by the Division of Health and Social Services, Massachusetts Committee on Public Safety, and is being distributed this week to all practicing physicians within the Commonwealth by the Massachusetts Department of Public Health. It should be especially suggestive and of interest to those physicians who work for a few hours daily, or only in a casual way, caring for industrially connected illnesses and accidents. The Committee on Industrial Health bespeaks the attention of all such physicians for this little publication.

DWIGHT O'HARA, *Chairman*

COMMITTEE ON MATERNAL WELFARE

CASE HISTORY: OPERATIVE DELIVERY FOLLOWED BY SHOCK AND DEATH

A twenty-eight-year-old primipara had been seen routinely during her pregnancy and had had adequate care. At the beginning of pregnancy, a blood Wassermann reaction had been reported positive, and in consequence of this, thirty injections of bismuth had been given; the Wassermann reaction at the end of pregnancy was said to have been negative. At this time, the systolic blood pressure rose to 130, and there was a trace of albumin in the urine. Labor started three days after spontaneous rupture of the membranes and lasted forty-one hours. Then, primary inertia of the uterus developed, and as full dilatation existed, forceps delivery was attempted. In spite of the fact that the head was low, delivery was so difficult that the fetus was decapitated, and extraction of the shoulders was accomplished only with great effort. The placenta was said to have been adherent, and was extracted manually. The patient died shortly afterward.

Comment. It is regrettable that any patient who had such intelligent and adequate care during the prenatal period should have been so mishandled at the time of delivery. It is, of course, possible that a so-called "dry uterus" resulted in a con-

traction ring and that this may have been the sole cause of difficulty. Or, if a contraction ring did exist, which seems likely, death may have been due to rupture of the uterus.

Intelligent obstetric management during labor would have obviated this maternal fatality. There is some question in the history regarding just when the death of the fetus occurred, but it apparently died during labor. If so, intelligent obstetrics should also have averted this disaster. Such bungling obstetric operating today is hardly understandable and certainly not to be condoned.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES June, 1942

Diphtheria was reported from: Boston, 1; Boylston, 1; Cambridge, 1; Fall River, 8; Medford, 2; Wrentham, 1; total, 14.

Dysentery, bacillary, was reported from: Beverly, 1; Waltham, 1; total, 2.

Encephalitis, infectious, was reported from: Leicester, 1; New Bedford, 2; Quincy, 1; Springfield, 1; Wellesley, 1; total, 6.

Malaria was reported from: Camp Edwards, 1; total, 1.

Meningitis, meningococcal, was reported from: Amesbury, 1; Beverly, 1; Boston, 3; Brockton, 1; Cambridge, 3; Chelsea, 1; Fort Banks, 1; Haverhill, 1; Hopkinton, 2; Medford, 1; Newton, 1; Peabody, 1; Taunton, 1; Wilmington, 1; total, 19.

Meningitis, other forms, was reported from: Beverly, 1; Boston, 2; Brockton, 2; Cambridge, 1; Dedham, 1; Foxboro, 1; Leominster, 1; Malden, 1; total, 10.

Paratyphoid infections were reported from: Boston, 1; Ludlow, 1; Medford, 1; Salem, 4; Watertown, 1; total, 8.

Septic sore throat was reported from: Barre, 2; Boston, 3; Cambridge, 1; Canton, 1; Malden, 1; Newton, 1; Waltham, 2; Winchendon, 1; Winchester, 2; Worcester, 1; total, 15.

Trichinosis was reported from: Stoneham, 1; Belcher town, 1; total, 2.

Typhoid fever was reported from: Fall River, 1; Woburn, 1; Worcester, 2; total, 4.

Undulant fever was reported from: North Andover, 1; Spencer, 1; Wilbraham, 1; total, 3.

Communicable diseases reported at figures above their respective five-year-average incidences included chicken pox, diphtheria, dog bite, scarlet fever, measles, German measles, syphilis, pulmonary tuberculosis, meningococcal meningitis and whooping cough.

Mumps was reported at a record-high figure for the tenth time during the past eleven months.

Anterior poliomyelitis reached a record-low figure with no new cases reported this month, for the first time since the disease was made reportable.

Reported at figures below their respective five-year incidences were bacillary dysentery, gonorrhea, paratyphoid infections, lobar pneumonia, tuberculosis (other forms), typhoid fever and undulant fever.

Cases of animal rabies were reported from Woburn and Attleboro, the former maintaining an old focus and the latter starting a new focus in the southeastern section of the State.

NOTES

The following promotions on the faculty and teaching staff of Harvard Medical School, effective July 1, were recently announced: George Van S. Smith, W. H. Baker Professor of Gynecology; Francis R. Dieuaide, clinical professor of medicine; Edward W. Dempsey, assistant professor of anatomy; Robert N. Nye, assistant professor of bacteriology and immunology; Austin M. Brues, assistant professor of medicine; Robert E. Gross, assistant professor of surgery; Frank W. Maurer, assistant professor of physiology; Madeleine F. Warren, assistant professor of physiology; Wilfred W. Westerfeld, associate in biological chemistry; John H. Dingle, associate in medicine; Charles A. Janeway, associate in medicine; Nathan B. Talbot, associate in pediatrics; Leslie Silverman, associate in industrial hygiene; and Joe V. Meigs, clinical professor of gynecology.

Dr. René Jules Dubos, member of the Rockefeller Institute for Medical Research, was recently appointed George Fabyan Professor of Comparative Pathology and professor of tropical medicine at Harvard Medical School. He succeeds Dr. Ernest E. Tyzzer, who becomes professor emeritus.

Dr. Eugene A. Stead, Jr., instructor in medicine at Harvard Medical School, was recently appointed head of the department of internal medicine at Emory University School of Medicine, Atlanta.

CORRESPONDENCE

SUSPENSION OF LICENSE

To the Editor: This is to inform you that at the meeting of the Board of Registration in Medicine held on July 17, 1942, the Board voted to suspend the license of Manford R. Spalding, 129 Central Street, Auburn, Massachusetts.

H. QUIMBY GALLUPE, M.D., *Secretary*

State House
Boston

REPORT OF MEETING

EVANS MEMORIAL LECTURE

At a Robert D Evans Memorial Lecture at the Evans Memorial, Massachusetts Memorial Hospitals, on March 27, Dr William Dock discussed Albuminuria and Associated Renal Changes.

In the many years between the original theories of Bright and the more recent observations of Addis, there has been little progress in this field. It was the keen observations of the little known Bostock, who did the actual urinalyses for Bright, that led to the latter's conclusions that albuminuria may result from many causes, most of them trifling, the albumin in the urine is that of the blood, the specific gravity of the urine is lower in drops, even in the presence of albuminuria, and albuminuria results in a lowered serum protein. These fundamental observations were not significantly enlarged on or their mechanism elucidated until various clearance tests and quantitative sediment studies were carried out recently by Addis.

It is still agreed that the causes of proteinuria are many and often trifling. Grossly, such kidneys are large, yellow and greasy. Microscopically, the tubules are full of fat. Originally, this substance was considered similar to that of the fatty degeneration of the brain, heart and liver, and this theory persisted until a few years ago. The glomeruli may look normal to the uninitiated but Bell in 1938, demonstrated that glomerular changes can in variably be found in post mortem examinations of persons over twelve years of age. In 1931, Marshall et al showed from comparative studies on fish that proteinuria is dependent fundamentally on glomerular damage. Ekelhorn confirmed the belief that the basic proteinuria is glomerular and that the tubules of such kidneys are called on to reabsorb large quantities of protein. The glomerular filtrate in frogs contains a higher percentage than bladder urine in severe damage, and the tubular changes may therefore be secondary.

Heymans demonstrated the tubular reabsorption of trypan blue and even a sort of phagocytic action on large foreign particles like those of India ink. In searching for a protein with a good distinguishing tag on it, Whipple hit on the use of hemoglobin. Injecting this substance, he determined that it does not appear in the urine until the concentration is over 100 mg per 100 cc. if the concentration is greater, hemoglobin spills over like a threshold substance in proportion to the serum concentration, and hemosiderin is found in the tubules like trypan blue. Only 3 per cent of the hemoglobin is found in the glomerular filtrate, compared with 30 per cent for such crystalloids as sugar, and it crosses even normal glomeruli. By this method, a dyed protein can be studied, and it is found that this one is a threshold substance, in all respects like sugar, with large amounts filtered and reabsorbed until the value exceeds the threshold. The glycogen in the tubules of diabetes is similar to the stored protein in proteinuria except for the different parts in which they are absorbed.

Known functions of the kidney include an ultrafiltration by the glomeruli and a reabsorption by the tubules of colloids, fine precipitates, water and crystalloids. The tubules also have some excretory function, notably of Diodrast, which amounts to almost 100 per cent. They also form ammonia and store iron and glycogen. To study the role of the kidney in regard to protein, a dye called Evans blue, which is taken up by protein, is used. This is passed by abnormal kidneys only, and then in proportion to the amount of protein. Even in the normal kidney,

a small amount of blue is noted in the tubules, although none is found in the urine. On the other hand, the tubules and urine are filled with the dye in proteinuria. This confirms the findings with hemoglobin and indicates that proteinuria is a result of glomerular dysfunction despite the fact that Richards et al have not been able to demonstrate the presence of protein in the glomerular filtrate.

But this method of microcannulation is inadequate to determine the small amount of protein expected. By perfusing of the kidneys with ice-cold serum, the material from the uterus is found to be identical with glomerular filtrate. Therefore, it is necessary merely to paralyze the tubules by this method and then remove the pelvic urine by ureteral catheterization. That no damage to the glomeruli results from this severe treatment is evident from the complete recovery of functions in animals that recover. By adding hemoglobin to the perfusion mixture, one can demonstrate that definite amounts of protein in about the concentration found in the cerebrospinal fluid can be collected (15 to 24 mg per 100 cc). The tubular reabsorption of fat and protein, therefore, is a normal phenomenon, and their presence in the tubules in large amounts is the result of overwork in an attempt to clear a heavily concentrated ultrafiltrate. It is not a true degeneration. The passage of protein in the urine occurs in inverse proportion to the size of the molecule, and it is too, is a glomerular function.

Clinically, there may be tubular paralysis allowing proteinuria similar to renal glycosuria. Table 1 indicates the average findings in certain renal conditions.

Early in renal disease, therefore, the tubules save the body a large amount of protein filtered by the glomeruli,

TABLE 1

CONDITION	GLOMERULAR FILTRATE		URINE	
	VOLUME liters	PROTEIN mg / 100 cc gm / day	VOLUME liters	PROTEIN mg / 100 cc gm / day
Normalcy	180	20 0.36	1.0	2 0.02
Mild nephritis	180	41 40	1.0	200 2.00
Severe nephritis	180	62 74.00	1.0	2000 20.00

but later they, too, leak. The threshold for protein seems to be about 40 mg per 100 cc in the normal and mildly diseased cases and 30 mg per 100 cc in the chronic and severe cases.

Tubular changes in proteinuria, therefore, are secondary. The tubules are overfed, not poisoned. Actual degeneration may also be present, especially in later stages of renal disease. The lipid tubular changes are the result of lipemia secondary to the low plasma protein. Why the glomerulus leaks has not yet been solved.

BOOK REVIEWS

The Medical Aspect of Boxing By Ernst Jöhl, MD 8°, cloth, 251 pp., with 55 illustrations and 4 plates. Pretoria South Africa J. L. Van Schaik, Limited, 1941 17s 6d.

This timely volume, devoted to a demonstration of the serious injuries sustained by professional boxers and, to some extent, amateurs as well, draws attention to matters very generally unknown and almost never discussed publicly.

The primary object is to prevent the known fatalities in the prize ring and their causes as revealed by autopsies and in other ways. The fatalities not occurring before the public and in the 'prize ring' are doubtless quite as numerous, for such occurrences would be likely to be ascribed to other causes, if reported at all.

In the professional field, boxing is the only sport in which the major competitive effort is directed to the adversary's head. The skull is more or less elastic and is of somewhat variable thickness in different persons. Hence, severe, individual blows on certain localities momentarily change the diameters of the cranial cavity; as a result, the soft contents may be so severely disrupted that serious hemorrhage occurs. This may be subdural or more deeply seated. Occasionally, there may be an actual skull fracture by *contrecoup*.

Aside from such tragedies, which are by no means unusual, statistics show that oft-repeated blows on the head result in a condition known as "punch drunk." This appears to be best explained by small multiple hemorrhages, scattered over and through the brain. About 5 per cent of all professional boxers suffer from it if they keep at the game long enough. Its symptoms are both physical and mental. Quite a considerable number of them require institutional treatment.

In addition to these major injuries, there are many others, some of which are nearly as serious.

The attitude of colleges and schools, athletic trainers and others concerning the value of boxing in courses of physical training was obtained through questionnaires and was rather illuminating in many ways. The brutalizing effect of the sport on certain of its professional exponents, as well as on the portion of the public that patronizes exhibitions, is emphasized.

The facts brought out by the author should give food for thought in wartime, when so many young men are being inducted into services in which boxing is regarded and encouraged as a desirable means of training. The book should have a wide circulation and careful consideration.

The Baker Memorial: A study of the first ten years of a unit for people of moderate means at the Massachusetts General Hospital. By Haven Emerson, M.D. 8°, cloth, 75 pp. New York: The Commonwealth Fund, 1941. 50c.

This is a carefully written survey of an institution unique in the annals of American medicine. The operation of the Baker Memorial has been a success, and after some misgivings, all physicians connected with it, as well as their patients, are nearly universal in approving the service rendered. Such an institution could be duplicated elsewhere in the country, but before doing so, as Dr. Emerson points out, many factors must be taken into consideration. Experience has shown that to be adequate in all respects, such a hospital must be an integral part of a large general hospital, must maintain a daily census of not less than 200 patients, and must have a bed-day rate of \$4.00 to \$6.00 and a capital investment of \$2,000,000; furthermore, the trustees must find an additional \$500,000 for an endowment fund to meet operating deficits in the first ten years. Any surplus should be used to improve service or reduce rates, the staff must submit to certain financial standards, and patients must be selected. Any community that wishes to provide a hospital for patients of moderate means will do well to consider with great care the report of the first ten years of the Baker Memorial.

The Story of Clinical Pulmonary Tuberculosis. By Lawrason Brown, M.D., 8°, cloth, 411 pp., with 1 portrait. Baltimore: Williams and Wilkins Company, 1941. \$2.75.

Few people are so well qualified to write the story of the evolution of clinical tuberculosis as the late Dr. Lawrason Brown. During his lifetime, he witnessed and contributed to the emergence of tuberculosis from a disease of despair to one in which early diagnosis could be estab-

lished with a high degree of certainty and treatment instituted on a rational and sound basis. Dr. Brown, more than anyone else, epitomized the scholar, the clinician, the teacher and the enthusiastic worker in the field of tuberculosis. It is therefore most fortunate that Mrs. Brown and a group of Saranac Lake physicians have painstakingly gone over his historical notes, compiled them in book form and handed them over for posterity as a monument to a truly great man; a debt of gratitude is due them.

The book, which is written in a very fluent and delightful story-telling style, can be read with equal enjoyment by the laity and the medical profession. The first four chapters describe visits to the tuberculosis experts of the period 1700 to 1900. In these chapters, the dramatic changes in the concepts of tuberculosis are given against the background of the Renaissance and the pulsating history of European events during that time. Part two of the book deals with Laennec and his successors and also considers the beginning of early diagnosis, early publications in Germany and Austria and the diffusion of knowledge in England, as well as a most complete and fascinating chapter on early diagnosis as it was developed in the United States. The chapter on diagnosis by x-ray methods was contributed by Dr. Homer L. Sampson, and the chapter on the development of surgical methods was written by that great pioneer in thoracic surgery, Dr. Edward W. Archibald, of Toronto. There are excellent sketches and sidelights on the life of Laennec and his writings on the story of the stethoscope and a description of early medical journals.

On the whole, this book constitutes the most comprehensive work on the history of pulmonary tuberculosis. Its story keeps the reader's interest from its very beginning to the end. This book will undoubtedly find its place among the best authoritative works on the history of medicine.

Biology of the Laboratory Mouse. By the staff of the Roscoe B. Jackson Memorial Laboratory. Edited by Dr. George B. Snell. 8°, cloth, 497 pp., with 172 illustrations and 37 tables. Philadelphia: The Blakiston Company, 1941. \$7.00.

The staff of the Roscoe B. Jackson Memorial Laboratory are to be congratulated on this very useful book. The editor makes the following significant comment in the preface:

"Because it deals with the mouse alone, this book presents a vertical cross-section of biological knowledge rather than the more usual horizontal cross-section. It contains information about one animal drawn from various branches of zoology, rather than information about one branch of zoology drawn from observation of a variety of animals."

There are thirteen chapters, which deal with the early embryology of the mouse, reproduction, histology, spontaneous neoplasms in mice, gene and chromosome mutations, the genetics of spontaneous tumor formation, the genetics of tumor transplantation, endocrine secretion and tumor formation, the milk influence in tumor formation, inbred and hybrid animals and their value in research, parasites, infectious diseases of mice, care and recording. The illustrations are many and good, the index is useful, and most valuable, perhaps, is the excellent bibliography at the end of each chapter. Every library should own a copy of this book, which deals with a mammal so widely used in all laboratories.

NUMBER 6

THE IMPACT OF THE WAR ON THE VENEREAL- DISEASE PROBLEM*

RAYMOND A. VONDERLEHR, M.D.†

WASHINGTON

THROUGH all history, syphilis and gonorrhea have been destroyers of the efficiency of armed forces. The story is familiar. During World War I, 6,800,000 man-days were lost in the United States Army because of venereal disease—equivalent to a year's absence from the service of 19,000 men. Actually, the number of new infections with venereal disease in the Army exceeded by 100,000 the number of battle casualties. Furthermore, in the Navy and the Marine Corps, 687,000 days were lost from duty because of venereal disease.

Material progress has been made in the fight against the venereal diseases, even though they have remained a major cause of noneffectiveness among the armed forces since 1918. This statement can be made in spite of the high prevalence of venereal diseases demonstrated by the routine serologic examination of selectees during mobilization for the present war. In the first million men, approximately 45,000 were found to have serologic evidence of syphilis or clinical manifestations of the primary and secondary stages of this disease.¹ An additional 15,000 were estimated to have gonorrhea. The preliminary data available on examination of the second million selectees confirm these figures. It would be extremely helpful to have available comparative data on the prevalence of syphilis in the men mobilized during World War I. The serologic test for syphilis in 1917 was new, expensive and technically much less reliable than at present. It was therefore not utilized routinely in the examination of the selectees, and a comparison cannot be made.

It is essential, however, to review some of the progress that had been made in the control of syphilis and gonorrhea before the beginning of the recent mobilization, that we may compare, in

the future, the control problems of venereal disease at the beginning and the end of the current war. Surveys² of sources of treatment in forty areas throughout the United States, representative of all sections of the country, were completed by the United States Public Health Service in 1935. Approximately 25 per cent of the total population of the country dwelt in these areas. The returns on these surveys included reports from more than 97 per cent of the treatment sources in such areas. The data available indicated that syphilis might be expected to strike one person in ten at some time during his life.³ A year ago, the most careful statistical studies utilizing the material available from the routine serologic examination of selectees showed that the chance of acquiring syphilis is about one in fifteen. Consequently, each person stood only half the chance of being infected with syphilis in 1941 that he did about ten years previously.

Massachusetts has taken first place many times in the syphilis-control program. It was first to require the reporting of syphilis as a communicable disease; first to provide serologic tests without cost; and first to distribute antisyphilitic drugs to private physicians. Its hospitals were encouraged early to start venereal-disease clinics. If Massachusetts were an island,—out of touch with infections from without,—it is probable that the control measures carried on so far would have been sufficient to reduce the prevalence of syphilis to the low prewar rate in Scandinavian countries.

In industry, great gains have been made in the solution of the syphilis problem. Prewar results of blood tests on applicants and employees in eighteen of the large plants of the E. I. du Pont de Nemours Company, for three periods since the beginning of their program against syphilis, provide an example. Tests made on 27,000 people by this company during 1934 and 1935 yielded a prevalence rate of 39 per thousand. The rate of 51,000

*Presented at the annual meeting of the Massachusetts Medical Society Boston, May 26, 1942

†Assistant Surgeon General, United States Public Health Service.

tests made in 1937-1938 was practically the same — 40 per thousand. But among 35,000 persons tested in 1940-1941, the rate dropped significantly — to 10 per thousand. Gehrman,⁴ chief industrial surgeon of this company, is of the opinion that this reduction in the prevalence of syphilis in widely scattered industrial plants was due primarily to insistence on regular treatment of infected employees. Similar reductions have been described by the surgeons of many other industries.

Even in the southern States, where the prevalence of syphilis had almost reached the saturation point, progress was made when the disease was attacked vigorously. As an example, in Glynn County, Georgia, where the first mobile unit for the control of syphilis was provided, the syphilis prevalence rate among Negroes in 1937-1938, the first year of operation of the mobile unit, was 391 per thousand.⁵ In the early part of 1941, however, the rate had dropped to 23.4 per thousand. In 1937, not one clinic patient in Glynn County had received the minimum treatment of twenty injections each of an arsenical compound and of bismuth. By March, 1941, 46 per cent of all patients admitted to the mobile clinic with early syphilis had received this protection. Most significant of all, the Negro stillbirth rate in this county has been reduced from 100 to 44 per thousand live births since the beginning of the syphilis-control program.

The first significant reversal of the downward trend in the venereal-disease rates was recorded recently when the Surgeon General of the Army reported that the admission rate for all venereal disease for the whole Army for the calendar year 1940 was 42.5 per thousand as compared with 29.6 in 1939.⁶ This trend upward has usually occurred in time of war and should stimulate an all-out application of every modern method for the control of the venereal diseases, in both the armed and the civilian populations. Provisions for early diagnosis and facilities for the institution of prompt treatment now exist in almost all areas with full-time local health services. The scarcity of trained personnel has handicapped the follow-up program, and some intelligence and ingenuity will be required to maintain the work at a satisfactory level. It may well be, however, that the solution of the war-time venereal-disease problem lies in individual prophylaxis. We must, as Lahey⁷ recommends, attempt to educate men to avoid venereal disease, but we must likewise understand that if this cannot be accomplished the necessity for prophylaxis must be promoted "even if it seems compromising to a sentiment." Today, as we are forced to spread even more thinly our supply of medically trained personnel, we must

not ignore the possibility of reducing case loads by taking every reasonable opportunity to prevent infections altogether.

One of the shocking revelations in the prostitution racket of recent years has been the participation of private physicians in the plunder. Time and again, where tolerated prostitution exists, the people in the community are given a false sense of security by being told that the prostitutes are rendered safe from venereal infections because they are subjected to periodic physical examinations. Much too frequently, reputable members of the medical profession perform these perfunctory examinations, and the prominence of the physician often lends support to the erroneous belief that this system is effective.

One among many instances can be cited that exemplifies the deplorable, yet profitable, part that private physicians have played in tolerated prostitution. Recently, the mayor of a city of about 50,000 openly supported a segregated area in which were located between 200 and 300 prostitutes. Nearby, the Army had concentrated men approximately equal to the total population of the town. The segregated district was doing a tremendous business, and the usual arguments against prostitution did not force the mayor to yield. He contended that the women in the area were examined periodically and were not the source of venereal diseases in the armed forces, although the Army rates were unusually high. Further investigation showed that the son of the mayor was a physician in private practice who was examining weekly the women in the segregated area at fees ranging from \$3.00 to \$5.00. It was not until the governor of the state brought pressure to bear on the mayor and his son that they could be persuaded to discontinue their support of the segregated area. The son, incidentally, was a reputable physician in the community and a member of the usual medical societies. Can we, as physicians, expect the public to take aggressive action against prostitution when some of the members of our own profession support the racket so flagrantly?

The routine serologic examination of selectees has produced a most serious problem of treatment and follow-up for infected men, who at the present time are excluded from military service. The record shows that serologic or clinical evidence of syphilis exists in approximately 45,000 of each million selectees examined under the Selective Service System. This rate holds true for the first and the second million, and it is estimated that within the next year 200,000 men with evidence of syphilis will have been discovered and excluded from military service. It is the obligation of the health officer and the physician in private practice to rehabilitate these syphilitic selectees.

Records showing the number of infected selectees brought under treatment throughout the United States are as yet incomplete. Steps are being taken to obtain better information as soon as possible. Present data available to the Public Health Service, however, show that on an average only half the infected selectees in the United States are being brought to treatment, and the percentage varies greatly in different sections of the country, depending on the existence of full-time local health services and a control problem for venereal disease well integrated with the local selective-service board. In many places with aggressive and efficient health officers, 100 per cent of the selectees are brought to treatment with the assistance of interested local selective-service boards. Other health departments do not do so well. When no health service is available, the entire responsibility for the treatment of infected selectees falls on the medical profession, and in such places, often only a very small fraction of the total infected selectees are brought in for examination and treatment. If during the next few years the numerous syphilitic selectees discovered through wartime examinations are given adequate treatment for their infections, one of the greatest accomplishments yet attained in the control of syphilis will have been made. If this opportunity is lost, however, it will constitute one of the greatest public-health and medical failures in the history of the United States.

In terms of relative prevalence, gonorrhea is four to eight times as common in the armed forces as syphilis. Comparative rates are not available for the civilian population, but it is quite probable that gonorrhea occurs there in much the same ratio. It is most discouraging that all health officers and physicians are not taking advantage of the modern

methods for the treatment and control of gonorrhea. Studies by the American Neisserian Medical Society, a great organization originally planned by the members of the Massachusetts Neisserian Medical Society, in co-operation with the United States Public Health Service, prove conclusively that there is no reason whatever for the high prevalence of gonorrhea if we will but apply present-day knowledge. Every man and woman with gonorrhea should receive the routine scheme of treatment recommended by the Executive Committee of the American Neisserian Medical Society.⁸

* * *

In all history, war has opened the gates to pestilence. Venereal disease strikes first, and its wounds are often the last to heal. At the present time, the United States is better prepared than ever before to wage an effective campaign against gonorrhea and syphilis. Tolerated prostitution and failure to apply promptly modern medical knowledge are the most vulnerable points in this field of medicine. Will the people of our democracy follow through against the venereal-disease foe within as efficiently as we will wage war against our enemies from without?

MASSACHUSETTS PUBLIC-HEALTH PROBLEMS IN WARTIME*

PAUL J. JAKMAUH, M.D.†

BOSTON

WARTIME demands on public-health services are compelling in their urgency. A people fighting for its existence scrutinizes each new activity with but a single thought in mind: will this add to our combined strength and further our effort in the ordeal that confronts us? Slowly but surely, we are coming to the realization that, remote as this present world conflict appeared at first, it has become a stark reality in the daily life of every one of us. Our present national responsibility is enormous. The responsibility of those of us engaged in public health is equally grave.

Under normal conditions, a critical appraisal of current activity and of new developments is a deserving procedure in any well-regulated health department. An evaluation of recent developments is particularly appropriate at this time. When existing resources are being taxed to the utmost, when so large a part of our national wealth is being devoted to the war effort, when increasingly severe burdens are being heaped onto our economic structure, it is extremely necessary that each new undertaking be examined in minute detail. In assuming new responsibility, our professional personnel must be utilized in the most efficient manner. Emphasis must be placed on those services most intimately and directly concerned with our national security. Our entire public-health program must comply with this ideal to ensure its permanency.

During wartime, increased attention must be given in public-health programs to those groups in the general population who bear the brunt of the burden. After a critical review of the high percentage of rejections for physical defects among young men examined under the Selective Service Act, we come to a realization of the need for increased health service for the youth of our nation. I say this although I realize that, to some extent, this high percentage of rejections is due to higher health standards for the acceptance of selectees than those in World War I.

Although it is true that many of the defects date back to inadequacies having their origin during infancy and early childhood, it is evident that increasing emphasis must be placed on the pres-

ervation of health during later childhood and adolescence.

No one can foretell the duration of this war. The high-school student of today may be the soldier of tomorrow. In industry, young girls in large numbers will take on themselves the responsibilities formerly assumed by men. The increase in tuberculosis among young women already noted in England is a warning that should not be allowed to go unheeded. Our present public-health program must include measures that will safeguard in every possible way all our people, with particular emphasis on those who are directly engaged in war efforts of one type or another.

Before outlining actual developments, I shall make several generalizations concerning the relation of the Massachusetts Department of Public Health to health authorities at various other levels. The department stands midway between local and national health organizations. In most of its functions, it acts as an advisory and investigative body. Actual legal health authority is most frequently vested in local boards of health, this being a natural development of local autonomy, the fundamental political concept in Massachusetts. Similarly, federal authority has been limited by the Constitution to certain specifically designated powers beyond which it is essentially advisory in character. With the passage of time, more specific duties have been delegated to health authorities at the federal and state levels.

During the last decade, this nation has been passing through a period of intense social reform. It is difficult to comprehend the vast transformation wrought by the Social Security Act. Titles V and VI of this act have had a profound influence on public-health practice throughout the entire country. State budgets have been augmented by federal funds. Existing services have been improved, and new ones added, according to definite stipulations by federal authorities regarding the manner in which this money may be expended. Title V funds pertain to maternal and child-health services and the crippled-children's program, and are under the supervision of the Children's Bureau of the United States Department of Labor. Title VI funds, which are for general public-health administration, are under the supervision of the United States Public Health Service.

As this nation passes from a peacetime to a wartime footing, the tendency for federal subsidi-

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1942.

†Commissioner of Public Health, Massachusetts Department of Public Health.

zation has become more marked. The proposed plan for rehabilitation of men rejected by selective service boards and the contemplated establishment of medical and public health services in federal housing projects indicate the interest that federal agencies are paying to state and local health problems. Bearing these considerations in mind, we may turn our attention to several of the more important developments in public health practices in Massachusetts.

In October, 1940, the first step was taken to establish the district health officer as the administrative co-ordinator or director of state health department programs in his district. Through the use of available personnel and in some instances the transfer of personnel, the health officer in the Worcester area was sufficiently equipped to carry out a complete public health program in his constituent communities. This plan of localization was extended in February, 1941, to the Greenfield area, and in the last few months, to the Springfield and Pittsfield areas. We are, at present, completing plans to handle the work in the southern area through an office in New Bedford. The remaining districts, those in and around the Metropolitan area and on the North Shore, will be organized as soon as practicable.

This so-called "district plan" provides office space and clerical assistance for the district health officer and various field personnel, such as public health nurses, nutritionists, and sanitary officers, medical social workers and others who have hitherto worked as individuals out of either the Boston office or their own homes. Such personnel is regarded as making up the staff of the district health officer, who is responsible for the administrative direction of their field work. Each district health officer will make every effort to apprise himself of the health needs and resources of the various communities in his district and will endeavor, through the efficient use of his staff, to find a solution for these needs.

We know that this change will tend to lend dignity and responsibility to the position of district health officer and will result in a reduction of duplication of effort on the part of the state personnel. It is particularly pleasing to me, and I am sure it should be to you, to realize that the state public health program is to be supervised in each district by the district health officer, a physician and fellow member of this society.

The district plan created a need for someone in the central office whose duty it would be to effect its success. Accordingly, the position, "assistant to the commissioner," was established and charged with the responsibility of local health administration. One of his tasks is to make certain that the district health officers and their staffs

function as desired and work as well co-ordinated field units. He must maintain close contact with the division directors, be familiar with their programs and make certain that they are completely and satisfactorily carried out by the district health officers and their staffs.

With the rapid growth and development of the public health nursing activities of the department and their extension into channels other than maternal and child health, it has long been deemed more practical to administer this program from the Division of Administration rather than from a specialized division of child hygiene. Consequently, the public health nurses have been transferred from each of the divisions concerned to the Division of Administration, where they are in a unit under the direction of a chief supervisor of public health nursing. Similarly, the supervisor of medical social service was transferred from the Division of Adult Hygiene to the Division of Administration.

Responsibility for the work of these units has been delegated to the assistant to the commissioner as part of local health administration. All the changes described are in line with public health practices in the majority of the other states and in accordance with the best administrative advice on the matter.

Another new activity is a study of ragweed eradication, which has assumed an ever increasing prominence as a public health problem, since it has been estimated that between 3 and 5 per cent of the general population is hypersensitive to wind-borne pollen. Because of its many public health aspects, the Legislature directed the department to make a study concerning the eradication and control of ragweed. Observations made under this study have disclosed that, in New England, ragweed is the only important factor in late summer and fall hay fever. In addition, the discoveries that during the late summer and early fall, pollen is encountered in the air in fairly even concentrations up to the height of one mile and that it is carried by the wind for many miles have revealed that, to be of any value, control programs require the active participation of neighboring communities throughout extensive areas. Small scale campaigns are absolutely futile. With the aid of all interested official and voluntary organizations, the study is being continued to obtain as complete information as possible. Data thus compiled will become the basis of recommendations to the Legislature for ragweed elimination.

Thus far, I have said very little regarding legislation. However, it should be of interest that on a national level a very high percentage of the pending bills concern health. I should like to sug-

gest that your committee on legislative matters be thoroughly alert to the trend, particularly on the federal level, to the introduction of legislation having to do with public health. Locally, during the last several years, the Legislature has seen fit to inaugurate new health laws and amend old ones. Inasmuch as it is impossible at this time to describe all the new laws that relate to public health, I shall outline briefly one or two of the more significant ones.

Up to January, 1942, there was no law that required the licensing of hospitals; hence, the supervision of general hospitals had never been allocated to any specific state agency. There were no standards concerning their construction or maintenance, except for local fire ordinances and zoning laws. It is quite obvious that such a system was open to many abuses. Although the state laws required that clinics and dispensaries be licensed by the Department of Public Health, maternity hospitals or wards by the Department of Public Welfare, and mental-disease hospitals by the Department of Mental Health, hospitals in general were not regulated. All this was quite illogical and was not conducive to the best interests of the public. If a license is necessary for one type of hospital, it is reasonable to expect that all hospitals should be licensed. The Legislature of 1941 remedied this situation by enacting a law that made it mandatory that general hospitals be licensed by the Massachusetts Department of Public Health. An advisory committee was appointed to assist the department in formulating the rules and regulations that are being established in connection with this work. Every effort and consideration will be made not to insist on unreasonable demands on hospital administrators.

The premarital health-examination law, with its amendments, became effective on November 1, 1941. Applicants for marriage licenses must present a health certificate signed by a physician practicing in Massachusetts or by a medical officer on active service with the armed forces of the United States. Certain aspects of the law are not entirely clear at the present time, but it is expected that future amendments to clarify them will be recommended by the department at the next session of the Legislature.

The immediate objective of the Department of Public Health is to stimulate and maintain vital health services, and I take this opportunity to assure you that, as a department, we are making every effort to concentrate on services that must be kept at a maximum level during the present emergency. To avoid duplication of effort in our defense work, all such activities are being organized in the Division of Administration. Every

effort is being made to save in the use of automobiles, and we have put a number of them into dead storage for use at a future time. We realize that there will be a tendency, for economical reasons and because of pressure of other business, to cut down on accepted public-health practices in many of the communities. We are striving to prevent this. Massachusetts enjoys an enviable record in communicable-disease control, environmental sanitation, nutrition, cancer control, and medical and surgical care. Our standards must not be lowered.

The district health officers have been appointed regional directors for health by the Massachusetts Committee on Public Safety, and so far as possible, their activities have been co-ordinated. Plans are being kept up to date for the immediate mobilization of the state health personnel in any part of the State, should this necessity arise.

The department is co-operating with the Army and Navy in an effort to control syphilis and gonorrhea in the armed forces and among civilians by providing an epidemiologic service whereby nurses connected with the department directly interview infected persons for the purpose of discovering the sources of infection and the places at which contacts or exposures occurred. The information acquired by this epidemiologic investigation is utilized by the armed forces, the Department of Public Health, police agencies and other interested groups in a co-operative effort to control genitoinfectious diseases.

My foregoing remarks have been confined principally to present or past work of the department. It may be well to mention briefly what our future programs may possibly include.

As you know, the department has participated in a study of a selected number of cases of arthritis at the Massachusetts General Hospital, and it is likely that an expansion of this type of activity will result in our making a similar study, in co-operation with recognized treating agencies, of cardiac conditions, which continue to be a major cause of death in the older age groups. For some time, we have been considering, and have submitted to this society, plans for a rheumatic-fever program, which would indeed be a worth-while activity. That the department may plan for increased facilities for custodial and palliative care of cancer patients, while they await admission to and after their discharge from the Pondville or Westfield hospitals, is also logical. The Kenny method for prevention and treatment of paralysis in anterior poliomyelitis might be the subject of detailed study and evaluation as part of our crippled-children's program.

Before concluding, I wish to state that, here in

Massachusetts, we have been very fortunate in being accorded the complete co-operation of the medical profession. I emphasize the facts that without this complete co-operation our enviable record in public health would have been impossible and that a satisfactory program for the future would be in serious doubt. Be assured, that, as public-health activities expand under the stimulation of

federal agencies, we shall keep in mind the physicians' interests and, through our district health officers, shall endeavor to keep you informed of changes as they are contemplated.

I sincerely hope that these few remarks will give you a better appreciation of our administrative organization, of some of our present activities, and of a few of our possible future channels of activity.

INDUSTRIAL HEALTH AND THE WAR*

DANIEL L. LYNCH, M.D.†

BOSTON

OUR country has a war to win. President Roosevelt has said that it will be won by industrial production, that is, by the production of overpowering numbers of planes, tanks and guns and all manner of weapons and ammunition, and of fighting ships and of freighters, to bring all these arms safely and abundantly across the seas that our allies and our gallant men around the world may victoriously finish the jobs they are about. It is apparent, therefore, that our sailors and soldiers on the firing lines and our "soldiers" in overalls on the production lines are entirely dependent on each other. If production fails, our army is without weapons; if our armed forces fail, the workers in industry will become workers in chains.

Thus, the worker in industry, not only in essential war industry, but in practically all industries,—because today nearly all are contributing something to the war effort,—has been given a place of special prominence in the war. His ability to measure up to it depends heavily on his physical fitness, his freedom from preventable disease and injury, his mental stamina and his morale. Thus, loss of working time, especially by skilled workers, no matter what the cause, must be regarded today as equivalent to casualties. It is therefore our patriotic duty as physicians to contribute our best efforts to the conservation of the health of these necessary men and women in industry, so that the loss of precious work hours may be minimized.

Probably, few persons, especially persons not in industry, fully realize the demand that this war has put on the industrial manpower of the country: to build up the armed forces and to produce all the material that the armed forces will need to win the war. And probably, few persons appreciate the magnitude of the losses of manpower

from industry incurred through accidents and, especially, nonoccupational sickness.

If plans progress as scheduled for this year, the Army will be increased to 3,600,000 men, and the Navy and the Marine Corps to 1,000,000 men, a total of 4,600,000 men, virtually all of whom will have been drawn from the main industrial force. Eventually, the Army may be increased to 8,000,000 or more men. And they are the men best qualified physically and mentally for industry. They have formed the framework of all industrial production.

In peacetime, 34,000,000 out of America's labor force of 52,000,000 persons are employed in industry. Of these, about 9,000,000 have already been shifted to direct war-production activities. Watchmakers have become blacksmiths, and dungarees have replaced white collars. The number must be increased this year to approximately 18,000,000 persons to meet the production schedules laid down by the President. War this year will be the business of more than 22,000,000 of our fellow citizens. It will mean that half of all the men in the country between the ages of twenty and sixty-five years will be in the armed forces or in war production before the end of the year. It will mean the continued shifting of industrial workers from peacetime pursuits to war production, to jobs with which they are unfamiliar and with hazards to their health and safety. It will mean the absorption into war industry of several million women now engaged in home duties or unemployed whose health deserves protection. It will mean the employment in industry of the somewhat reckless young men and women between seventeen and nineteen years of age,—major accident risks,—of men past sixty years of age and of many physically handicapped persons—girls without fingers or with immobile hands and fingers, one-eyed persons and the like. It will mean that industries not directly engaged in war production, but nevertheless essential to the war effort, such as agriculture and the public serv-

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 27, 1942.

†Medical director, New England Telephone and Telegraph Company.

ices, and industries essential to the preservation of civilian morale will absorb the less physically able to work of America's labor force. It will mean an appreciable increase in accidents, occupational diseases and nonoccupational illnesses unless adequate protection for the health and safety of all these workers is provided.

Our country has the manpower and the womanpower to win this war, if they are kept vital. Therefore, industrial health becomes an acute problem: the world's greatest production unit must continue to emit the deep and resonant hum of machinery working at full efficiency.

When Japan sneaked into Pearl Harbor, everybody was grievously shocked by the report that 2600 young men had been killed. Few of us, however, are seriously impressed by the very much larger number of fatal and other accidental injuries daily occurring in civilian life—a most unfortunate situation in these days when every available man is needed, and when every hour counts in our industrial production for war.

The aggregate loss of manpower from industry because of accidents arising out of and in the course of employment is startling.² It is generally estimated that actual lost time owing to temporary disabilities sustained in occupational accidents in the United States averages at least 800,000 days each week,² or approximately 40,000,000 days each year. That equals the work days required to produce over three thousand bombers. Last year, 18,000 persons were killed in occupational accidents, and more than 90,000 others suffered permanent disabilities. Together, these accidents account for the loss of approximately 4,000,000 workdays each week, the workdays necessary to build eight destroyers.² But the time losses in industry caused by nonoccupational, off-duty accidents are far greater than all the losses due to occupational accidents and occupational diseases combined; in fact, they are more than twice as high.

Huge as these losses of vital man-hours sabotaged by accidents may appear to be, they account for only a small fraction of all the lost time in industry. Nonoccupational diseases, all the ills of the body and of the mind and the emotions to which the human flesh fell heir, deprived industry last year of approximately 3,000,000,000 work-productive man-hours, or nearly 400,000,000 work-days. Some of the loss is, of course, unavoidable, some of it can be salvaged through better placement of the worker and by preventive medicine and co-operation from the private physician, and some of it, unquestionably, can be saved by stimulating greater loyalty to the job in this critical hour. If we could save even a tenth of this lost

time due to sickness, the need for long hours of work and the seven-day week could be materially reduced, the vicious circle between fatigue and lost time broken, and production definitely increased.

These are the problems of industrial health—occupational accidents, occupational diseases, off-

FIGURE 1. *Distribution of Lost Time (1936-1940).*

The cases include those of occupational accidents with one or more days of lost time and those of nonoccupational accidents or sickness with eight or more days of lost time.

duty accidents and nonoccupational sickness. Industrial health and industrial efficiency go hand in hand. If industrial health breaks down, production will fail. If production fails, the boys who fell at Pearl Harbor, at Bataan and at Corregidor will have made the supreme sacrifice in vain.

To maintain industrial health at a productive level is the province of industrial medicine. Industrial medicine may therefore be regarded as the science that deals with prevention, alleviation and cure of diseases that affect gainfully employed persons.³ It is a field of special medical interest comprising the practice of medical-department administration, medical supervision, preventive medicine, toxicology and public health within the confines of industry.³ Its objectives⁴ can be accomplished by the prevention of disease or injury in industry through the establishment of proper medical supervision over industrial materials, processes, environment and workers, by the health conservation of workers through physical supervision and education and by medical and surgical care to restore health and earning capacity as

promptly as possible following industrial accident or disease.

No revolutionary changes in well-managed industrial health programs for peace are required to remodel them for production for war. Health

FIGURE 2. Frequency of Medical Diagnoses in Illnesses of More Than Two Days' Duration (1941).

measures that have long been recommended and used successfully in large industries should be applied with greater interest and renewed vigor and more extensively to include the small plants of 500 or less workers, where about 70 per cent of all industrial workers are employed, and where there is good reason to believe that the individual worker is exposed to more hazards or to the same hazards in more ways than the man in the large plant, because their frequency and severity rates of accident are definitely higher.

The major health measures⁴ may be enumerated as follows:

Prevention. The physician should acquaint himself, by regular inspections, with all materials and processes used in the working environment over which he has supervision, to the end that he may recommend appropriate protection of workers from conditions actually or potentially harmful.

Prevention requires provision for a safety organization with a definite and active program in accident prevention, which includes close supervision of the new inexperienced worker and the placing of the accident-prone worker in less dangerous jobs. All workers should be trained in first aid. (At the end of June, 1942, we shall

have completed the training of nearly 8000 telephone workers in five New England states in the standard first-aid course of the American Red Cross.)

Industrial physical examinations. Preplacement physical examinations should be used to fit each person to a type of work that he is able to perform continuously without undue impairment, without injury to himself or to his fellow workers and with profit to himself and to his employer. Rejections should not exceed 3 per cent.

Subsequent physical examinations should be complete enough to provide positive health protection for all workers and to safeguard public

MEN AND WOMEN

FIGURE 3. Frequency of Medical Diagnoses in Severe Illnesses of More Than Two Days' Duration (1941).

welfare. Repetition of such examinations should be governed by the circumstances of exposure and health.

Health education. The plant physician should take advantage of all opportunities for instruction of the workmen in hygienic living, both in and out of the industrial environment.

Medical and surgical care. In the treatment of compensable injuries and diseases, the disabled worker, after first-aid care, should be free to choose his physician from all those licensed doctors of medicine competent to supply the required services. The plant physician should co-operate to the end that no reasonable medical, surgical, hospital or consultative expense is spared to ensure a good end result.

The treatment of injuries or diseases not industrially induced is the function of private medical practice. In his industrial relations, the physician should abstain from such services except for minor ailments (the physician in industry may treat minor physical disorders that temporarily interfere with a worker's comfort or ability to complete a shift, and for the relief of which he may need immediate attention), first aid for urgent sickness (the physician in industry should employ such measures as the emergency dictates in all cases of urgent sickness occurring during working hours on working premises until such time as prompt notification of the family physician or family relieves him of responsibility) and rehabilitation after sickness and injury (the physician in industry can properly assume responsibility for those phases of rehabilitation after disability, industrially induced or otherwise, that progress best under controlled working conditions).

The physician in industry should be a specialist in his field. In addition to a good training and experience in the general practice of medicine and surgery and to good personal qualities, he should possess a knowledge of the detection and control of occupational diseases and be able to locate hazards and to study the earliest symptoms caused by them. He should become experienced in case

of his problems are personal as well as medical. He should know job analysis, to assist in the proper placement of new workers and in the rehabilitation and proper placement of the injured, of the worker with arrested tuberculosis and of those handicapped by heart disease, hypertension, arthritis and other chronic diseases. He should have a knowledge of factory laws and records, of compensation laws, of plant sanitation, ventilation and illumination, of accident prevention and safety and of humanitarianism. He should have had special training quite beyond the field of private practice.

War production has placed special emphasis on the factors of fatigue and nutrition for industrial workers. It is known from Britain's experience⁵ after Dunkirk that production, through the medium of the twelve-hour day, seven-day week, increased for a short time, but that accidents increased two and a half times. Within two months, production started to fall and absenteeism became general, owing in part to the fatigue or exhaustion of the workers. In 1941, a committee of the House of Commons reported that absenteeism, even during the winter, dropped about 35 per cent when the working day was reduced to eight hours.

Fatigue, in its physiologic and its psychologic aspects, is perhaps the greatest problem facing the physician in industry today. More and more, it

FIGURE 4. Frequency of Medical Diagnoses, According to Sex, in Illnesses of More Than Seven Days' Duration (1936-1940).

finding in communicable disease and its control. He should possess a knowledge of administration, which includes industrial relations, because many

will sabotage the output of American industry unless we profit by the experience of our allies, who had to learn the lesson by trial and error.

If all of us, particularly private practitioners, who after all, will continue to treat nearly 85 per cent of all disabilities, industrially induced or

day, the forty-hour week, the machine age, "Beauty-Rest" mattresses and other "take-it-easy" creature comforts have made "softies" out of too

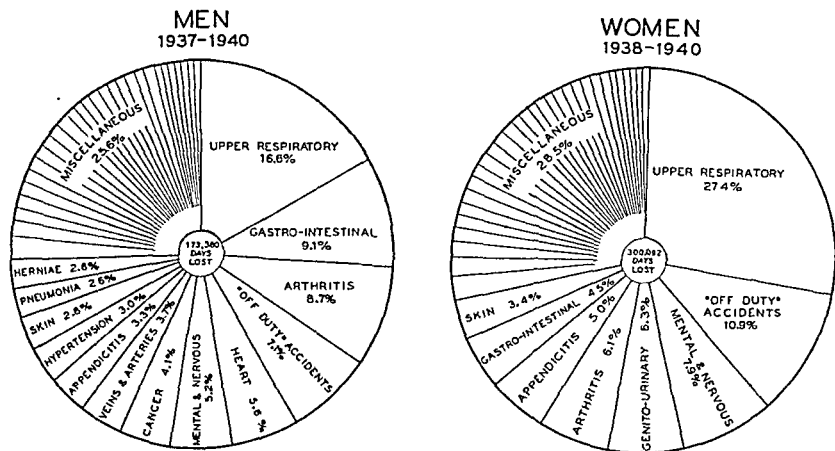

FIGURE 5. Frequency of Medical Diagnoses, According to Sex, in Severe Illnesses of More Than Seven Days' Duration.

otherwise, will give serious thought, firstly, to the great need for production to win this war and,

many of us. Perhaps, less automobiling and more footwork will make for less coronary-artery fat,

FIGURE 6. Cases of Sickness Disability, According to Age and Sex, per 1000 Workers (1936-1940).

secondly, to the reduction of industrial lost time, the need for the seven-day week and the twelve-hour day can be materially reduced. For after all, we, as a people, "can't take it" any better than our British allies: unemployment, the short work-

disability and death, and for a stronger generation to follow.

Malnutrition is a fifth columnist that erodes our war-workers from within, and works on three eight-hour shifts to produce an industrial slow-

down: insidious and unseen, it may well be an underlying cause of absenteeism, industrial accidents and lowered production. It has been clearly demonstrated that persons on deficient diets soon

There is just a little more to wartime industrial health, as suggested by Dr. Elton Mayo, of the Harvard Business School. Industry must abandon the philosophy of "take care of the technical situa-

FIGURE 7. Percentage of Total Calendar Days Lost Owing to Sickness Disability, According to Age and Sex (1936-1940).

develop fatigue, mental depression, general weakness and loss of morale. Inadequate facilities for

tion and let humanity handle itself." It must realize "that sentiment is perhaps more important

FIGURE 8. Distribution of Cases of Sickness Disability by the Day Absence Began, According to Sex (1936-1940).

lunch and insufficient time for eating are, at the present time, justifiable causes for dissatisfaction among workers in many plants and on all shifts.

than logic in dealing with workers; that the men at the bench have feelings other than those expressed in terms of hours and wages, that they need social

recognition in the shop quite as much as they need it in the neighborhoods where they live." The maintenance of good mental health and of good morale is extremely vital to the industrial physician. He must continue his efforts to put humanitarianism into war production activities.

May we, as private physicians and industrial

Figure 3 shows the severity of disabilities lasting two or more days in the same group, these lay-offs accounted for approximately 155,800 lost days in 1941. Again, upper respiratory infection was responsible for a third of all lost time.

Figure 4 shows the frequency of medical diagnoses among men and women when the absence

physicians, team up so that production for war may be kept rolling, around the clock!

* * *

Some of the problems of industrial health are illustrated by the accompanying charts, which are based on figures obtained by my department of the New England Telephone and Telegraph Company and from the Consolidated Edison Company, New York City.

Figure 1 shows the distribution of industrial lost time between occupational and nonoccupational accidents and nonoccupational sickness. It should be noted that 86 per cent of 16,648 disability cases were due to nonoccupational sickness that lasted eight days or more, 10 per cent to nonoccupational accidents and only 4 per cent to occupational accidents causing disability for one day or more. Occupational accidents seem to have been well controlled.

Figure 2 shows the frequency of medical diagnoses in illnesses lasting more than two days in a group of 19,500 cases. Upper respiratory infections were responsible for 48.5 per cent of all these cases of disability, and all efforts to better the situation have thus far been futile.

continued for eight or more days. In both groups, disabilities due to upper respiratory infections caused the highest number of absences, as was true in the short period absences. Disability due to off-duty accidents formed the second largest group among women, and the third largest group among men.

Figure 5 shows the severity of the various types of disabilities. As one would expect, the proportion of all lost time because of upper respiratory infection was less among women and among men than the proportion of actual absences, since disability is shorter in upper respiratory illness. But it should again be noted that off-duty accidents among women caused nearly 11 per cent of 300,000 lost days from work, and that, among men, they caused 7 per cent of 173,000 lost days. In both groups, arthritis caused an appreciable amount of lost time.

Figure 6 is evidence of the increasing frequency of disability for work among men and among women as age increases. In the age group from twenty to twenty-nine, there were roughly 70 cases of disability per 1000 men per year, whereas among men over sixty, approximately 200 cases occurred per 1000 men. Among women, the contrast was

not so great, but there is pictured the upward trend of disability frequency as women advance in age. This increase was consistent from year to year, and it emphasizes the problem of industrial health as it is affected by the older employees.

Figure 7 demonstrates the severity of illness with increasing age; although men under thirty lost only about 0.7 per cent of available work time because of illness, men over 60 lost nearly 5 per cent. The situation was similar among women, the length of their absences increasing with age, regardless of its cause.

Figure 8 is interesting. It shows the frequency with which absences began on the several days of the week. One wonders why such a large proportion of all disabilities began on Monday. It may be that workers did not feel quite up to par at the end of the week, but remained on to finish out the week; or it may mean that a good many of them had a "bad week end."

More interesting, however, is Figure 9, which indicates the day of return to work following disability, regardless of the day on which disability began.

Among men, nearly 70 per cent returned to work on Monday, and the same thing was true for nearly 60 per cent of the women. Production must continue on other days of the week, as well as on Monday, and those concerned with production cannot understand why workers who have recovered from illnesses wait until Monday to return to work. To a large extent, it is a psychologic problem—the thought of beginning the week right. Unquestionably, the private physician can help a great deal in this respect: a great deal of lost time can be regained if he will permit and encourage his patients to return to work as soon as they are able.

ROBERT BURTON AND HIS DRUGS: THE ARMAMENTARIUM OF 1600*

CLIFFORD S. LEONARD, PH.D.†

BURLINGTON, VERMONT

IN THE second partition of Robert Burton's *Anatomy of Melancholy*, which appeared in London in 1621 and in which the author dealt with the cure of melancholy, one finds a discussion "of Physick which cureth with medicines, and of medicines purging melancholy and of those curing head melancholy and hypochondriacal or windy melancholy."

Burton was not a physician, but he was a learned man who had read the works of those before him and of his contemporaries, and had sifted out the gist of their recommendations. At that time, the doctrine of the four humors and the temperaments prevailed, and there was no science of anatomy or of physiology for physicians. Vesalius had begun to influence surgery, but internal medicine remained medieval.

Burton began by railing at physic a bit:

The country people use kitchen physick and common experience tells us they live freest from all manner of infirmities that make least use of apothecaries physick. . . . Some think the physicians kill as many as they save and who can tell how many murders they

make a year, *quibus impune licet hominum occidere*, that may freely kill folk and have a reward for it? And, according to the Dutch proverb, a new Physician must have a new Church-yard, and who daily observeth it not?

However, after further such diatribe, he hastened to say: "But I will urge these cavelling and contumelious arguments no farther, lest some physician should mistake me and deny me Physick when I am sick; for my part, I am well persuaded of Physick."

Burton proceeded to single out some of the chief and best recommended drugs of the pharmacopeias and herbals at his disposal. He divided all simple medicines into alteratives and purgatives. It is his list of simples that is considered here. He had comparatively little use for compound formulas or for powdered precious stones, although he devoted a small space to them. The purgative simples were divided into those purging upward (emetics) and those purging downward (cathartics). He also divided the simples as having particular virtues for particular parts of the body:

As to the head, Aniseeds, Foalfoot, Betony, Calamint, Eyebright, Lavender, Bays, Roses, Rue, Sage, Marjorum, Peony, etc.; for the lungs, Calamint, Liquorice, Enula

*From the Department of Physiological Chemistry and Pharmacology, University of Vermont College of Medicine.

†Assistant professor of pharmacology, University of Vermont College of Medicine.

Campana, Hyssop, Horehound, Water Germander, etc., for the heart, Borage, Bugloss, Saffron, Balm, Basil, Rosemary, Violet, Roses, etc.; for the stomach, Wormwood, Mints, Betony, Balm, Centaury, Sorel, Purslain; for the liver, Dartsipine, Germander, Agrimony, Fennel, Endive, Succory, Liverwort, Barberries; for the spleen, Maidenhair, Finger-fern, Dodder of Thyme, Hop, the rind of Ash, Betony; for the Kidneys, Grumel, Parsley, Savitragre, Plantain, Mallow; for the womb, Mugwort, Pennyroyal, Fetherfew, Savine, etc.; for the joints, Camomile, St. John's Wort, Organ, Rue, Cowslips, Centaury the less, etc.

How many of Burton's drugs have persisted through the ages? How many were official in the pharmacopoeia and formularies as late as the turn of the twentieth century? I have made a list, finding for Burton's old common names the

Latin names of his galenicals, and then determined whether they were in the *U. S. Pharmacopoeia VII* (1894) and whether they are still in the *U. S. Pharmacopoeia XI* (1936) or in the *National Formulary V* (1926) or *VI* (1936). I also consulted certain editions (1914, 1926 and 1932) of the *British Pharmacopoeia*. Furthermore, by referring to the 1894 edition of the *U. S. Dispensatory*, as well as the 1938 edition, I ascertained whether the drugs that were not in the official and semiofficial lists chanced to be mentioned in Part II of these dispensatories. The citation of Burton's drugs in Table 1 may not be complete, but the one hundred and thirty-eight items given suffice to demonstrate how Burton's drugs have withstood the centuries.

TABLE 1. *Burton's Drugs and Their Survival to Modern Times.*

LATIN NAME	BURTON'S NAME	MODERN NAME (IF DIFFERENT)	BURTON'S THERAPEUTICS	MODERN THERAPEUTICS

<i>Ambergris</i>	Ambergris		For flatulence	Disp 1938 antispasmodic
<i>Ammi cistraga</i>	Ammi	Bishop's weed	For flatulence	Disp 1938 stomachic
<i>Ammonium chloridum</i>	Ammonic	Ammonium chloride	Mild purge	USP 1936 saline; expectorant
<i>Amomum melegueta</i>	Grana paradisi		For flatulence	Disp 1938 stomachic, spice
<i>Anacyclus pyrethrum</i>	Pellitory		Masticatory	USP 1894 rubefacient, analgesic
<i>Anchusa officinalis</i>	Bugloss		For melancholy, for the heart	Disp 1938 stomachic, diuretic
<i>Anethum graveolens</i>	Dill		Diuretic	B P 1926 diuretic
<i>Angelica archangelica</i>	Angelica		For flatulence	Disp 1938 stomachic
<i>Anthemis nobilis</i>	Camomile		For the joints, for flatulence	USP 1894, BP 1926 stomachic
<i>Antimonium sulfidum</i>	Antimony	Antimony sulfide	Emetic	BP 1926 emetic
<i>Aristolochia rotunda</i>	Aristolochy	Somewort	For flatulence	Disp 1938 tonic
<i>Artemisia abrotanum</i>	Southernwood		For baths	Disp. 1938 mentioned
<i>Artemisia alcyonanthum</i>	Wormwood	Absinthe	For the stomach	Disp. 1938 stomachic
<i>Artemisia vulgaris</i>	Mugwort		For melancholy, for the uterus for the spleen	Disp 1938 ecboic
<i>Arum maculatum</i>	Dragon's root	Cuckoo's pint	Mild purge	Disp 1938 expectorant
<i>Asarum europaeum</i>	Asaribacca, foet's foot	Asarum	Emetic, for the head, diuretic	Disp 1938 emetic, errhine
<i>Asplenium ceterach</i>	Ceterach, finger fern		For the spleen	Disp 1938 other <i>Asplenis</i> mentioned, probably antihelmintic
<i>Atropa mandragora</i>	Mandrake		For sleep	Disp 1938 depressant (atropine and mandragorine)
<i>Berberis vulgaris</i>	Barberry		For the liver	BP 1914, NF 1936 astringent, cathartic
<i>Betonica officinalis</i>	Betony		For the head, for the stomach, for the spleen	Disp 1938 aromatic; astringent
<i>Borago officinalis</i>	Borage		For the head, for the heart	Disp 1938 demulcent
<i>Brassica nigra</i>	Mustard		For flatulence	USP 1936 condiment, emetic
<i>Coffea arabica</i>	Coffee		For the head	NF 1926 stimulant, flavor.
<i>Calendula officinalis</i>	Marigold		For melancholy	USP 1894, NF 1936 antispasmodic
<i>Cannabis sativa</i>	Hemp, living	Indian hemp	For sleep	BP 1926, NF 1936 hypnotic
<i>Carum curvi</i>	Cary	Caraway	For flatulence	USP 1936 stomachic
<i>Caryophyllus aromaticus</i>	Clove		For flatulence	USP 1936 carminative
<i>Cassia fistulosa</i>	Cassia		Purge	USP 1894, BP 1932, NF 1926 purgative
<i>Cassia senna</i>	Senna		Purge	USP 1936 purgative
<i>Castor</i>	Castor	Glands of beaver	For melancholy, errhine	Disp 1938 antispasmodic
<i>Chicorium endica</i>	Endive		For the stomach	Disp 1938 mentioned
<i>Chicorium intybus</i>	Chicory, succory		For melancholy	Disp. 1938 reputed tonic, in jaundice
<i>Cnicus benedictus</i>	Carduus benedictus	Thistle	Emetic	Disp 1938 emetic
<i>Colchicum autumnale</i>	Hemodactylis	Colchicum	Purge	USP 1936 in gout, palliative
<i>Colutea arborea</i>	Colutea	Bladder senna	Mild purge	Disp 1938 purgative
<i>Combretacea Terminalis</i> (5 species)	Mirbalant		Purge	Disp 1894 astringent, cathartic
<i>Convolvulus scammonium</i>	Scammony		Purge (by suppository)	Disp 1938 purge (Mexican scammony, an <i>Ipomoea</i> , in NF 1936)

TABLE 1 (Continued)

LATIN NAME	BURTON'S NAME	MODERN NAME (IF DIFFERENT)	BURTON'S THERAPEUTICS	MODERN THERAPEUTICS
<i>Crocus sativa</i>	Saffron		Soporific, for the heart	USP 1894, NF 1936 coloring matter
<i>Curcuma zedoaria</i>	Zedoary		For flatulence	NF 1926 aromatic, for flatulence
<i>Cuscuta epithymum</i>	Epithyme dodder of thyme		For the spleen	
<i>Cuscuta europaea</i>	Dodder		Mild purge	
<i>Cyclamen hederacfolium</i>	Ciclimen	Sow bread	For flatulence, purge	Disp 1938 purgative
<i>Datura stramonium</i>	Datura stramonium	Thorn apple jimson weed	For melancholy	USP 1936 nerve depressant
<i>Daucus carota</i>	Daucus	Carrot seed	Diuretic	Disp 1938 diuretic
<i>Dictamnus albus</i>	Dittany		Purge of melancholy	Disp 1894 sedative in hysteria
<i>Drosera rot. solis</i>	Ros solis	Sundew	For melancholy	Disp 1938 other <i>Drosera</i> cited as inert
<i>Electuarium lentium</i>	Confection of senna		Lentive purge	USP 1894 BP 1932 mild purgative
<i>Eleitaria repens</i>	Carduans	Cardamom	For melancholy, for flatulence	USP 1936 aromatic, carminative flavor
<i>Eruca sativa</i>	Rocket		Aphrodisiac	
<i>Erythraea centaureum</i>	Centaury		Mild purge	Disp 1938 tonic, laxative
<i>Euphorbia lathyris</i>	Caper	Caper spurge	Purge	Disp 1938 diuretic, oil, a cathartic
<i>Euphrasia officinalis</i>	Eyebright		For the head	Disp 1938 reputed for toothache, eyes and catarrh
<i>Foeniculum vulgare</i>	Fennel		For the liver, diuretic	USP 1894, NF 1938 (oil), USP 1936 aromatic carminative
<i>Fraxinus excelsior</i>	Rind of ash	Ash bark	For the spleen	USP 1894 for rheumatism and gout
<i>Fraxinus ornus</i>	Manna		Purge	USP 1894, NF 1936 gentle laxative
<i>Fumaria officinalis</i>	Fumitory		Purge	Disp 1938 tonic laxative
<i>Genista tinctoria</i>	Genist	Broom dyer's broom	For flatulence	Disp 1938 purgative
<i>Globularia alypum</i>	Alypus	Wild senna of Europe	Purge for flatulence	Disp 1938 mild purgative
<i>Glycyrrhiza glabra</i>	Liquorice		For the lungs	USP 1936 flavor, demulcent
<i>Gururcum</i>	Gururcum		For melancholy	NF 1936 anarset, purgative
<i>Helleborus niger</i>	Black hellebore		Drastic purge	Disp 1938 emetic cathartic cardiac
<i>Hepatica triloba</i>	Liverwort	Hepatica	For the liver	Disp 1894 tonic astringent demulcent
<i>Humulus lupulus</i>	Lupulus	Hops	For the spleen for the blood for melancholy	USP 1890 NF 1936 tonic, bitters
<i>Hypericum perforatum</i>	St. John's wort		For melancholy, for the joints	Disp 1938 reputed in hysteria and mania
<i>Hyssopus officinalis</i>	Hyssop		For the lungs for flatulence	Disp 1938 carminative expectorant
<i>Inula helenium</i>	Enula campana	Elecampane	For flatulence	USP 1894 expectorant
<i>Juniperus sabina</i>	Juniper berries, sabine		For the uterus, for flatulence	USP 1936 (oil) carminative diuretic
<i>Ipomoea turpenthum</i>	Turbeth	Turpenth	Purge	BP 1932 purge (jalap group)
<i>Lactuca sativa</i>	Lettuce		Sedative	Disp 1938 inert
<i>Lapis Armenum</i>	Armenian stone		Simple purge	Disp 1894 Armenian bole mentioned as an antacid
<i>Lapis lazuli</i>	Lapis lazuli		Purge	Lazurite contains sodium sulfide and aluminum silicate
<i>Laurus nobilis</i>	Laurel or bay	European laurel	Emetic	Disp 1938 spice, stomachic
<i>Lavandula vera</i>	Lavender		For the head	USP 1936 (oil) aromatic stimulant flavor
<i>Laterdula stoechas</i>	Stoechas		Mild purge of melancholy	Disp 1894 tonic stomachic
<i>Lithospermum officinale</i>	Gromel	Gromwell	For the kidneys	Disp 1938 reputed diuretic
<i>Malia sylvestris</i>	Willows		For the kidneys	Disp 1938 demulcent, sometimes used in kidney disease
<i>Maranta galanga</i>	Galanga or China root		For flatulence	Disp 1938 stimulant, aromatic
<i>Marrubium vulgare</i>	Horehound		For the lungs	USP 1894 tonic, laxative for cough
<i>Melissa officinalis</i>	Balm		For the head, for the heart	USP 1894 diaphoretic, antispasmodic
<i>Mentha pulegonium</i>	Pennyroyal		For the uterus for flatulence	Disp 1938 stomachic, abortifacient
<i>Mercurialis annua</i>	Mercury herb		Purge	Disp 1938 diuretic
<i>Myristica fragrans</i>	Nutmeg		Soporific, for flatulence	USP 1936 aromatic, flavor, sedative eccubolic
<i>Nicotiana tabacum</i>	Tobacco		Emetic	USP 1894 emetic
<i>Nymphaea odorata</i>	Water lily		Soporific, anaphrodisiac	Disp 1938 reputed anaphrodisiac
<i>Ocimum basilicum</i>	Ocyme or basil		For the heart	Disp 1938 aromatic, condiment demulcent
<i>Origanum vulgare</i>	Origan or marjoram		For the joints for flatulence for the head	Disp 1938 tonic, condiment stomachic
<i>Paeonia officinalis</i>	Peony		For melancholy, for the head	USP 1894 antispasmodic, in epilepsy
<i>Papaver somniferum</i>	Poppy	Opium	Soporific	USP 1936 narcotic
<i>Petroselinum hortense</i>	Parsley		For the kidneys	USP 1894 echolic, antipyretic
<i>Pimenta officinalis</i>	Allspice		For flatulence	USP 1894 NF 1936 carminative
<i>Pimpinella anisum</i>	Anise seed		For flatulence, diuretic	NF 1936 (oil) carminative flavor
<i>Piper nigrum</i>	Pepper		Irrhine	USP 1894, NF 1936 carminative sternutatory
<i>Plantago major</i>	Plantain	Plantain	For the kidneys	Disp 1938 diuretic (Psyllium seed NF 1938 purgative)
<i>Polypodium vulgare</i>	Polypody	Polypody fern rock brake	Purge	Disp 1938 pectoral, demulcent, purgative, antelmintic?
<i>Polyporus officinalis</i>	Agaric	Agaric mushroom	Purge	Disp 1894 anciently reputed in consumption
<i>Portulacca oleracea</i>	Purslain		For melancholy	Disp 1938 diuretic?

TABLE 1 (Concluded)

LATIN NAME	BURTON'S NAME	MODERN NAME (IF DIFFERENT)	BURTON'S THERAPEUTICS	MODERN THERAPEUTICS
<i>Primula officinalis</i>	Primrose cowslip			Disp 1938 mentioned
<i>Pyrethrum (Chrysanthemum) parthenium</i>	Fiebitefew, feverfew		For the uterus	Disp 1938 action like camomile
<i>Rheum officinalis</i>	Rhi barb		Purge	USP 1936 purgative
<i>Rosa centifolia</i>	Rose		For the head	USP 1894 NF 1936 (<i>rosa gallica</i>) as tringent tonic
<i>Rosmarinus officinalis</i>	Rosemary		For flatulence	USP 1936 (oil) aromatic stimulant
<i>Rumex acetosa</i>	Sorrel	Dock	For the stomach	Disp 1938 astringent diuretic
<i>Ruta graveolens</i>	Rue		For flatulence	Disp 1938 astringent diuretic
<i>Salix alba</i>	Willow		For sleep	Disp 1936 contains salicin
<i>Salvia officinalis</i>	Sage		For flatulence for the head	NF 1936 astringent aromatic flavor
<i>Santalum album</i>	Sanders	Sandalwood	For melancholy	USP 1894 NF 1936 expectorant aromatic
<i>Sassafras sarisfolium</i>	Sassafras	Sassafras	For flatulence	USP 1936 (oil) aromatic carminative flavor
<i>Satureja hortense</i>	Calimint		For the head for the lungs	Disp 1938 mentioned
<i>Satyrion</i>	Satyrion	An orchid	For the head	
<i>Saxifrage cordifolia</i>	Saxifrage		For the kidneys	Disp 1938 a litter
<i>Scolopendrium vulgare</i>	Scolopendria		For the spleen	Disp 1894 astringent demulcent
<i>Scorzonera hispanica</i>	Bliss salisy		For melancholy	
<i>Smilax china</i>	China	China root	For melancholy	Disp 1938 diuretic
<i>Smilax officinalis</i>	Sarsaparilla		For melancholy	USP 1936 diuretic, for syphilis
<i>Sodi nitratis</i>	Saltpeter	Sodium nitrate	Purge	USP 1926 saline cathartic diuretic
<i>Solanum dulcamara</i>	Solanum	Nightshade	For sleep	NF 1936 sedative
<i>Sonchus oleraceus</i>	Sow thistle		For the blood	Disp 1938 cathartic
<i>Tamarix gallica</i>	Tamarisk	Larch	For the spleen	EP 1914 astringent, expectorant
<i>Taraxacum officinale</i>	Dandelion		For the blood for melancholy	USP 1894 NF 1936 bitter, stomachic
<i>Terebinthina</i>	Cyprian turpentine	Turpentine	For flatulence	NF 1936 not recommended internally
<i>Teucreum chamaedrys</i>	Germander		For the lungs	Disp 1938 corroborant
<i>Teucreum scordium</i>	Scordium	Winter germander	For the lungs	Disp 1938 corroborant
<i>Thymus vulgaris</i>	Thyme		Preparative	NF 1936 (oil) pectoral
<i>Urginea vcratima</i>	Scilla sea onion	Squills	Emetic	USP 1936 emetic cardiac
<i>Urtica dioica</i>	Nettle seed		For flatulence	Disp 1938 diuretic
<i>Valeriana jatamansi</i>	Spiknard (oil)		For flatulence	Disp 1894 expectorant
<i>Valeriana officinalis</i>	Valerian		For flatulence	USP 1936 sedative of smooth muscle
<i>Valeriana album</i>	White hellebore		Emetic errhine	Disp 1938 emetic cardiac (1 <i>viride</i> in USP 1936)
<i>Verbasca</i>	Verbascum	Mullen		NF 1926 demulcent
<i>Vitex agnus castus</i>	Agnus castus		For flatulence	King's 1m Disp 1898 anaphrodisiac
<i>Viola odorata</i>	Violet		For the heart	Disp 1938 demulcent laxative emetic
<i>Zingiber officinalis</i>	Ginger		For flatulence	USP 1936 aromatic spice

One concludes from the above list that, of the one hundred and thirty-eight drugs, fifty-eight were still official or semiofficial in 1890, whereas fifty of these have persisted to the present decade. Of the rest, all but about six are described as drugs in a modern source, the *Dispensatory*.

Burton lived just before the influx of drugs from the Americas, when such important items as quinine and ipecac arrived—long before Withering and his digitalis, and longer still before Claude Bernard and the beginning of experimental medicine. But, for Burton's day, this was a sane list, amid many semimagical offerings. True, he mentions one author who praises the virtue of taking one hundred and one eggs, three at a time, but with the knowledge of vitamins today, eggs in such large "doses" might have some therapeutic effect. He mentions the virtue, at seasonable times, of being seasick.

It seems remarkable that there existed therapeutic nihilism, too, before his time, for Burton quotes an author (Girolamo Cardan, 1501-1576) who could "cure all diseases with water alone."

Does that not sound like the present school whose dictum is "rest and forced fluids"?

No wonder Burton spurned compound formulas, the "dia-this" and "dia-that," the confections, the electuaries, the theriaca (treacles) and the mithridates. The following is the formula* of the

R	Gm vel cc
Trochique of squills	360
Trochique of the bodies of vipers	180
Hedycroon	
Long peppers	
Tl elacic op um	150
Red roses	
Dried glycyrrhiza	
Turnip seed	
Water germander	
Balm of Gilead	
Cinnamon	
Agaric	aa 90
Costus root	
Ind in pard	
Dicamnis of Crete	
Rhapontic	
Cinquefoil root	
Ginger	
White marubium	
Arabic stoechas	
Flowers of fragrant jonquils	
Macedonian parsley seed	

*This is taken from the second edition of a French work, *Pharmacopoeia Rosale Galeni que et Chymique* (Lyon 1753), by Moyse Charas and is one of the traditional formulas for this medicament. The first edition of Charas's work was issued in Paris in 1766 and thus may have been seen by Burton. The formula made 40 pounds but the pharmacist doubtless did not set about making up this item too often.

Mountain calamin		
Aromatic coffee		
Saffron		
Black and white pepper

Good honey		12,684
Good wine	q.s.	

Make a treacle according to the art.

Sig: Take one teaspoonful at bedtime, followed by a glass of wine. Two teaspoonfuls may be taken if necessary.

"Theriaca of the Elder Andromanchus," originally in Latin, which has been translated into English and the metric system.

The indications were paralysis, apoplexy, epilepsy,

lethargy, convulsions, diarrhea and dysentery, as a vermifuge, as an antidote to poisons, for malaria and pest smallpox, against the bites of mad dogs and snakes, for insomnia, for hysteria, for icterus and for "infinite other maladies." Each 75 gr. was stated to contain 1 gr. of opium. Hence, a teaspoonful would give about 0.06 gm. opium, or a full adult dose.

One did not in those days compound such a treacle in the amount of a single prescription. One can think of the assistants pounding mortars for days before the assembly of the mixture.

Accordingly, Burton did not hold theriacas in repute, and it can be seen why. He preached moderation. And, strangely enough, in therapeutics, he found authority for this in the writings of Arnold of Villanova, who lived from 1235-1312. Burton quotes Arnold as follows:

And this no other which I say than that which Arnoldus prescribes in his 8 Aphoris: *A discreet and godly Physician doth first endeavor to expel a disease by medicinal diet, then by pure medicine*, and in his 9th: *he that may be cured by diet must not meddle with Physick*. So in Aphoris 11: *A modest and wise Physician will never hasten to use medicines, but upon urgent necessity, and that sparingly too*.

Can those who today teach pharmacology and therapeutics think of a better tag for the end of their course of lectures, a better *envoi* to the students, than these words of Arnold's from the year 1300?

MEDICAL PROGRESS

NUTRITION: THE APPEARANCE OF THE TONGUE AS AN INDEX OF NUTRITIONAL DEFICIENCY*

HAROLD JEGHERS, M.D.†

BOSTON

THE old-time practitioner paid considerable attention to the appearance of the patient's tongue; much helpful information was undoubtedly secured. It is the purpose of this review to point out that the modern physician can use this simple clinical observation to a much better advantage than his predecessor.

In his recent monograph, Thoma¹ states, "The tongue is probably a better indicator of somatic disturbances than any other part of the oral mucosa." The literature of the last ten years indicates this to be especially true for the various nutritional deficiency disorders. To clarify this aspect of the subject, it is necessary to review briefly the anatomy of the tongue and the lingual manifestations of systemic disorders, as well as primary lingual diseases that may be confused with the manifestations produced by the nutritional deficiencies.

Diagnostic Importance of Tongue In General Practice

Changes in the tongue are numerous and reflect, or are actually diagnostic of, many systemic disorders other than nutritional deficiencies. Means,² Comroe³ and Kennedy⁴ have briefly discussed some of these. The monographs by Prinz and Greenbaum⁵ and Thoma⁶ do so in greater detail and include many colored plates of representative lesions. A study of these plates is helpful, since the color of lingual lesions is often of prime value in diagnosis and yet very difficult to visualize from a written description. The tongue reflects the degree of jaundice, pallor or cyanosis, at times of pigmentation and more rarely of purpura. Changes in taste or in movement and the onset of paralysis or tremors are of value in neurologic diagnosis. The tongue is enlarged in cretinism, myxedema, mongolism, acromegaly, angioneurotic edema, infectious glossitis and so forth. Rarely, one may see the Lubarsch-Pick syndrome (systematized amyloidosis with macroglossia).⁷ The Liebermeister syndrome is diagnostic of air embolism.⁸ A num-

ber of dermatologic conditions have associated lingual lesions, as do certain of the blood dyscrasias, drug eruptions and uremia. Dameshek and Henstell⁹ have emphasized the characteristic appearance of the tongue in polycythemia vera. McCarthy,¹⁰ Comroe³ and Brown and Haffner¹¹ have discussed some of the commoner disorders localized in or peculiar to the tongue. These include leukoplakia, cancer, chancre, tertiary syphilis, lingual thyroid, benign tumors, traumatic ulcers, glossitis rhomboidea mediana and so forth. These conditions, even though numerous and varied, are usually distinctive in appearance and can be readily differentiated from the lingual changes due to nutritional deficiencies. The latter are discussed in detail elsewhere in this paper.

Simple inspection with the naked eye or with an ordinary magnifying glass (2 or 3x) gives all the information required. Trueblood¹² advises that the tongue be palpated with the gloved fingers. This procedure, by evaluating the degree of induration, is helpful in diagnosing cancer, chancre and so forth, but is not required to detect the changes caused by the deficiency states. Glossitis and other lingual changes should be differentiated from buccal mucositis,[‡] gingivitis and cheilitis.

Anatomy of Tongue

The ability of the tongue to reflect so many systemic changes is inherent in the unique histologic structure of the dorsum of the tongue anterior to the V-shaped groove, the sulcus terminalis of His, which separates the anterior from the posterior portion or root. The undersurface of the tongue is covered by thin, smooth mucous membrane identical in structure, appearance and color with the rest of the buccal mucosa. The mucous membrane of the posterior dorsum of the tongue is thick, freely movable and of clinical interest only because of the numerous lymphoid follicles (lingual tonsil) present there.¹⁴

*The term, "stomatitis," is commonly used in the literature to include involvement of the mucous membrane of the tongue, buccal mucosa, mucosa of the palate, gums and lips in a process resulting from irritation, infection or deficiency. The epithelium of the buccal mucosa, palate and undersurface of the tongue is different from that of the dorsum of the tongue. One may be involved without the other and certainly may differ in its response to the same exciting pathologic agent. Since there is no suitable term (comparable to glossitis for the dorsum of the tongue) to signify involvement of the mucous membrane of the buccal mucosa, palate and undersurface of the tongue, Weinberger¹³ suggests buccal mucositis as an appropriate term. Gingivitis (for the gums) and cheilitis (for the lips) are, of course, well understood.

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume of *Medical Progress Annual*, Vol. III, 1942 (Springfield, Illinois: Charles C. Thomas Company, 1942, \$5.00).

†From the Robert Dawson Evans Memorial, Massachusetts Memorial Hospitals, the Fifth and Sixth (Boston University) Medical Services, Boston City Hospital, and the Department of Medicine, Boston University School of Medicine.

‡Assistant professor of medicine, Boston University School of Medicine physician, clinical staff, Evans Memorial, Massachusetts Memorial Hospitals, junior visiting physician, Boston City Hospital.

The anterior dorsal covering of the tongue is adherent to the muscular tissue and consists of a corium or mucosa rich in vessels, nerves and lymphatics covered by stratified squamous epithelium, similar to but thinner than the skin, arranged for the most part as numerous papillae. There are eight to twelve large, round, circumvallate papillae arranged in a V just anterior to the sulcus terminalis. Most of the anterior dorsum is covered with numerous filiform papillae, thin, barblike squamous epithelial projections. They hide the underlying vascular mucosa and, being relatively opaque squamous cells (similar in a lesser capacity to those that make the skin appear white), give the tongue its normal whitish-pink color in contrast to the red color of the lips and buccal mucosa. There is a continual regeneration and shedding of the squamous epithelium of these papillae similar to the squamous cells of the skin.

The fungiform papillae appear as rounded bright-red eminences among the whitish-pink filiform barbs, larger but much fewer and sparser on the dorsum than at the tip and edge of the tongue. The fungiform papillae appear red because the capillary-containing mucosal portion is covered by only a thin layer of epithelium in contrast to the thicker epithelial layer of the filiform papillae. The epithelium of the filiform papillae appears sensitive to many metabolic changes; it may proliferate more rapidly, making each papilla appear whiter and thicker, or desquamate more readily, exposing the underlying mucosa. The latter condition gives the tongue a smooth red appearance and renders the red fungiform papillae more prominent. The epithelium of the fungiform papillae is more resistant to such changes. The circumvallate papillae are affected least of all.

Dry Tongue

Means² has stressed the fact that dryness of the tongue is "the best clinical index of the state of hydration of the body," especially if oliguria, with urine of high specific gravity, is a concomitant finding. The simplicity of lingual inspection makes this a most valuable bedside observation. Mouth breathing, although likely to dry the surface, does not give the tongue the dry, shriveled appearance of a true dehydration. Gregersen and Bullock's¹⁵ demonstration of a close correlation between the volume of the plasma and the flow of saliva appears to give scientific support to the above clinical axiom. Kirk,¹⁶ on the other hand, was unable to correlate the plasma chloride concentration or the degree of dehydration with the condition of the tongue. He believes that dryness of the tongue is better correlated with the degree of intestinal motor paralysis.

The problem is further complicated by the repeated observation that dryness of the tongue often accompanies glossitis, especially that due to deficiency of nicotinic acid¹⁷ and probably from other factors of the vitamin B complex as well. The tongue becomes moist again following appropriate vitamin therapy. Invariably, such persons have atrophic glossitis. Although the mechanism is not clear, it appears that one may expect to see dryness of the tongue in deficient vitamin states as well as in dehydration. Nicotinic acid has been reported as a successful remedy for xerostomia—a condition characterized by chronic dry mouth.¹⁸

Coated Tongue

The coated tongue has probably occasioned more concern in the layman's mind than in medical circles. Interpreted in the light of modern knowledge, the coat on the tongue may have diagnostic and prognostic significance with relation to the deficiency disorders. Essentially, the coat on a tongue consists of increase and thickening of the desquamating squamous epithelium of the filiform papillae, in addition to mucin, food debris, mouth organisms and leukocytic exudate caught on or between the filiform barbs. The color is white, but may be changed by tobacco, coffee, food or medicinal substances and so forth, since the desquamating epithelium is more readily stained than other cells. A slight coat on the tongue is a common normal finding, especially on the less mobile posterior portion. Failure of the self-cleansing mechanism of normal mastication and salivation causes it to increase. Indeed, a unilateral coating may be noted when half the tongue is immobilized by paralysis.⁴ When dehydration is severe, the coating may become dried and matted together, giving the *encrusted tongue*.

Rhoads¹⁹ believes that, in some cases at least, the old-fashioned coated or furred tongue represents beginning necrosis of the filiform papillae. As the condition progresses, the coating becomes more marked until finally the epithelium of the papillae desquamates, leaving the typical slick, red atrophic surface of a vitamin B complex deficiency glossitis. It is a well-confirmed observation that a coated tongue is rarely seen in any of the forms of atrophic glossitis. When therapy is given, the papillae grow in again. The return of a normal surface makes a coating again possible. In other words, the integrity of the papillae is necessary for a coat on the tongue. An increase in the coating may indicate an early deficiency state, and a smooth tongue, with the absence of any coating, an advanced deficiency condition.

A noticeable coat on the tongue is common in many infectious diseases, probably most notably in

scarlet fever. Within forty-eight hours in this disease, the engorged and enlarged red fungiform papillae protrude above a thick white lingual coat caused by hypertrophy and increased desquamation of the filiform papillae to give the characteristic *strawberry tongue*. Then follows desquamation of the white filiform barbs, revealing a smooth, somewhat granular purplish-red lingual mucosa—the typical *raspberry tongue*. The resemblance of this raspberry tongue to the magenta glossitis of ariboflavinosis has aroused comment, but proof of this etiology is lacking. Within a week or more, the papillae of the scarlet-fever tongue regenerate, with return of the normal lingual appearance.

One may speculate on the possibility that infectious diseases influence the lingual papillae by interfering with proper metabolism of the various factors of the vitamin B complex. The lingual coat in scarlet fever may be more striking than in other infectious diseases because the enanthem operates in addition to the mechanism just mentioned. Resolution of this problem may prove to be a fruitful bit of research.

Oatway and Middleton²⁰ found a correlation of coated tongue with the degree of gastric acidity. Of 55 patients with coated tongues, 11 had achlorhydria, 2 hypochlorhydria, 17 hyperchlorhydria, and 25 normal acidity.

Pellagrous Glossitis

Spies and Cooper,²¹ in their review of the clinical features of pellagra, stress the frequency and severity of glossitis and include a colored plate of the most typical lesions. Others give similar descriptions.^{22, 23} Early, there is swelling and redness of the tip and lateral margins of the tongue, and the papillae may be engorged; atrophy of the papillae may follow later, but is not prominent early. The reddening assumes a fiery-scarlet hue. Ulcerations may form, and often become covered with a greyish membrane in which Vincent's organisms may be found. Swelling, tenderness, pain and salivation may be prominent.¹⁷ If the condition persists, the papillae may atrophy, and the tongue may become dry.¹⁷ The dramatic response to niacin (nicotinic acid) therapy—with blanching of the redness within twenty-four hours and the healing of atrophic or ulcerative areas, and even disappearance of the associated Vincent's infection, in forty-eight to seventy-two hours—leaves no doubt about the specificity of this type of glossitis.

A somewhat similar type of glossitis, but not accompanied by the other usual clinical features of pellagra, has been frequently reported, often in epidemic proportions, in such varied places as Palestine,²¹ China,¹⁷ India^{23, 26} during the siege of Madrid²⁷ and elsewhere.²⁸ The glossitis in these

epidemics usually, but not always, responded to niacin therapy. These so-called "epidemics" occurred when large numbers of people were fed insufficient amounts of the same kind of food. This type of glossitis was in a sense considered "larval" pellagra.

Field, Parnall and Robinson²⁹ stress the fact that in the Northern part of this country pellagra is often atypical in appearance and different from the full-blown classic syndrome seen in the South. Lesser changes than a red, sore, atrophic tongue may be present. Sometimes, the tongue is merely swollen, somewhat painful and showing indentations from the teeth. At times, the lingual changes are those seen in the nondescript atrophic glossitis, which is described in a later section. The non-lingual aspects of this atypical pellagra syndrome are described in detail. This concept of pellagra is of special interest to the practitioners of New England.

Riboflavin-Deficiency Glossitis

The distinctive features that characterize the lingual changes attributable to riboflavin deficiency were first described by Jolliffe, Fein and Rosenblum³⁰ and Kruse, Sydenstricker, Sebrell and Cleckley.³¹ In contrast to the fiery-red color of pellagra, the tongue in ariboflavinosis is magenta or purplish red. The epithelium over the papillae does not desquamate, but appears flattened and edematous, with resultant "mushroom-shaped" papillae that give the surface of the tongue a finely "pebbled" or granular appearance. Hence, the synonyms—pebbled tongue, granular tongue and magenta tongue—applied to this form of glossitis. Fissures may develop. The tongue may be painful, may have a burning sensation, and may even cause some dysphagia on swallowing. These lingual changes may precede and almost constantly accompany the cheilosis and seborrheic dermatitis of this deficiency state. Features of riboflavin deficiency helpful to diagnosis have been reviewed elsewhere.³² Sydenstricker et al.³³ noted frequently that the red and atrophic tongue of pellagrins treated with niacin, with diets low in riboflavin, changed, over a period of weeks, to a magenta glossitis that, in turn, cleared up when riboflavin therapy was instituted. Weisberger,³⁴ on the other hand, believes that the glossitis of riboflavin deficiency is characterized by a primary lingual coating followed by a patchy oval desquamation, with the center atrophic and the edges whitish pink and raised. He believes that the specificity of these changes rests on their improvement with riboflavin therapy. However, this is not the generally accepted point of view.

The cause of the magenta color in the riboflavin-deficient tongue is not clear. Sydenstricker et al.³³

studied the dorsum of these tongues in living patients with a microscope (magnification, 20x) and described the flattened papillae as "looking more like a dead jelly fish that has been washed up on the beach than anything else, a round translucent hemisphere with the capillaries lying deeply in a loose coil."

A logical explanation for this color change appears as follows: capillary dilatation and proliferation are prominent features in ariboflavinosis and undoubtedly take place in the mucosal portion of the papillae. If the capillaries are dilated, one may postulate that the circulation of red corpuscles through them may be slowed. The overlying epithelium is not desquamated but thinned and perhaps edematous. These dilated capillaries, with their stagnant blood flow seen through the changed epithelium, give the resultant magenta color to the tongue. The rapid blanching of the tongue following riboflavin therapy further supports this explanation. The normal tongue, in contrast, has a pinkish-white color because the underlying capillary loops of the mucosal portion of the papillae are covered by a partially opaque stratified squamous epithelium. The tongue in niacin deficiency and in the commoner atrophic glossitis, on the other hand, is scarlet or beefy red, because the overlying epithelial cells of the papillae desquamate, causing the capillary loops in the mucosal base of the papillae to be more prominent and their color more apparent. In addition, there seems to be a capillary response similar to inflammation in niacin deficiency.

Glossitis From Other Deficiencies

Lingual changes due to deficiencies other than niacin or riboflavin undoubtedly occur, but are, as yet, not well delineated. There appears to be no oral lesion characteristic of thiamine deficiency. Glossitis did not develop in human subjects placed on a thiamine-deficient diet.³⁵ There is the suspicion that vitamin A deficiency may produce hyperkeratotic changes in the oral mucosa.

Rosenblum and Jolliffe²³ noted cases of glossitis that failed to respond to niacin or riboflavin but improved with the use of vitamin B₆ (pyridoxine). They believe there may be lingual changes characteristic of pyridoxine deficiency. These tongues are described as smooth, slightly edematous, occasionally painful and of a peculiar purplish hue. Unfortunately, the full acceptance of this important observation is conditioned by the suggestion of others that pyridoxine may be necessary at times for the utilization of riboflavin.³³ Deficiency of other less well-known fractions of the vitamin B complex may cause lingual changes. This possibility is suggested by the response of glossitis to yeast or liver extract after failure to respond to

the well-known pure vitamins such as riboflavin and niacin.³⁶ The cause of glossitis in pernicious anemia is not entirely certain.

Waldenström and Hallen's³⁷ studies indicate that iron deficiency may cause lingual changes that revert to normal with the use of iron alone. Glossitis is frequently present in the idiopathic hypochromic anemia of women,³ an iron-deficiency disorder.

There is some evidence that the use of the estrogens either increases the demand for or suppresses the utilization of the vitamin B complex. Ashworth and Sutton³⁸ reported that the administration of estrogens to persons with a subclinical vitamin B complex deficiency produced glossitis as well as other lesions characteristic of a complete deficiency in the vitamin B complex.

Hunter's Glossitis

Hunter,³⁹ in 1909, studied the glossitis of pernicious anemia, attributing it to an infectious process. As late as 1927, Schneider and Carey⁴⁰ presented evidence to support this. Although the tongue in pernicious anemia may become infected secondarily, there seems but little doubt that the glossitis is on a deficiency basis. Lewis,⁴¹ in 1930, summarized the evidence for this. It is a clinical characteristic of pernicious anemia that the glossitis accompanies relapses and clears with control of the anemia.

The subjective complaints of pain, burning and numbness are often a prominent feature, even at a time when gross changes are minimal, being especially prominent when spicy, salty or hot foods are placed in the mouth. Occasionally, small vesicles are noted about the edges that may break down and form tiny ulcers. The description of atrophic glossitis to follow later applies as well to Hunter's glossitis. A striking feature in severe relapses of pernicious anemia may be the contrast of the red atrophic tongue against the pallor of the buccal mucosa.

According to Castle,⁴² the cause of glossitis in pernicious anemia is not entirely certain but, as suggested by the high incidence of achlorhydria in this disease, is conditioned by the absence of the so-called "gastric intrinsic factor." Thus, the glossitis of patients with pernicious anemia does not respond to experimental therapy with beef muscle unless normal human gastric juice is given simultaneously. In certain cases of sprue, however, the glossitis may improve with beef muscle alone, presumably because of the natural presence of gastric intrinsic factor.⁴³ Ventriculin and liver extract, which are effective remedies for the sore tongue in these conditions, so act because they contain a product of the interaction between a

food factor and gastric intrinsic factor derived from the normal animal. Castle⁴² does not believe that the glossitis in pernicious anemia has any features that separate it from other forms of glossitis. Manson-Bahr⁴⁴ goes even farther: he believes that a glossitis of similar nature and nonspecific to the disease is found not only in pernicious anemia but also in sprue, pellagra, nutritional anemias and idiopathic steatorrhea.

Restoration of the tongue to normal, with regeneration of papillae, commonly follows the remission of pernicious anemia with liver extract therapy. This process has been followed objectively with the use of tongue prints.²⁰

Myxedema (especially when anemia is prominent) and pernicious anemia are often confused with each other and may actually coexist. Means⁴⁵ points out that a red atrophic tongue is common in myxedema and increases the difficulty of this differential diagnosis. The person with myxedema is likelier to have a large clumsy tongue, pain being a less prominent feature, in contrast to the smaller but more painful tongue in pernicious anemia.

The term Hunter's glossitis may appropriately be applied to the lingual changes of pernicious anemia, but it implies no distinctive features of specific diagnostic value. The complaint of a sore tongue and the finding of glossitis suggest the diagnostic possibility of, but do not prove, the presence of pernicious anemia. All the diseases mentioned in the section on atrophic glossitis must be considered in the differential diagnosis.

Moeller's Glossitis

Moeller's glossitis, also known as glossitis marginalis exfoliativa or chronic superficial excoriations of the tongue, appears to be a poorly defined lingual condition that may be related to some deficiency state. Prinz and Greenbaum⁵ consider it synonymous with Hunter's glossitis of pernicious anemia. Thoma,⁶ on the other hand, believes it to be of varying etiology, and includes allergy, drug eruptions and neural disturbances as possible causative factors in addition to nutritional deficiency.

It consists of irregular, but well-defined atrophic areas, which are limited most frequently to the sides and tip of the tongue, are bright red, are never coated and are persistently painful. In fact, pain appears to be one of the most prominent features and is made worse by acid or hot foods, spices and so forth. It may be confused with "wandering rash" of the tongue. From the nutritional point of view, Moeller's glossitis appears to be a painful form of atrophic glossitis, the areas of atrophy being limited in extent and most fre-

quently localized to the lateral edge and tip of the tongue. Its characteristics appear too indefinite for one to consider it a distinct entity.

Atrophic Glossitis

An atrophic glossitis not readily recognizable as due to any specific vitamin deficiency appears to be a common clinical finding. It is variously called atrophic glossitis, bald tongue, slick tongue, bald tongue of Sandwith, beet-red tongue and beefy-red tongue. Rhoads¹⁹ expressed his inability to predict which therapy would be effective from the appearance of the tongue. Since in clinical practice deficiencies are multiple, it is to be expected that most cases of glossitis will be of complex origin and not one of the clear-cut specific lingual syndromes previously described.

This type of glossitis^{2-4, 6, 20, 46-48} begins with desquamation of the epithelium of the filiform papillae at the tip and sides of the tongue. At times, small vesicles form and break down. The affected area appears red (atrophic), and may be painful if the desquamation is deep enough. Later, the filiform papillae over the dorsum desquamate. The tongue then appears red and smooth, with the fungiform papillae still prominent. Even the latter may eventually flatten and disappear. At this stage, the tongue has the appearance of a piece of raw red meat. The papillae are said to regenerate in the reverse order with appropriate therapy. These tongues may be dry, and at times some loss of taste is experienced. Because the circumvallate papillae seem to escape gross changes, the gustatory sense is not noticeably altered. If the tongue is slightly swollen, impressions from the hard palate and teeth may be noted on the dorsum or edges. Frequent comment can be found concerning the absence of a coat on the atrophic tongue.

Usually, the nature of the deficiency cannot be told from the appearance of the tongue. However, Kuo and Huang¹⁷ believe that niacin deficiency is a main, but not necessarily the sole, feature when ulcers are present and inflammatory changes (scarlet hue) with minimal papillary atrophy are prominent findings in the glossitis. Atrophy of the papillae, with but little inflammation (a smooth pinkish-red tongue), is more suggestive of a liver-extract deficiency. Patients with atrophic glossitis should be treated with the whole vitamin B complex, that is, yeast or crude liver extract, in addition to such pure vitamins (riboflavin, niacin and so forth) or iron as seem indicated by the clinical evidence for their deficiency. Disappearance of the glossitis with regeneration of papillae has been noted in from five to thirty days in many patients thus treated.

Glossitis of this type has been noted in^{3, 4} pernicious anemia, sprue, achlorhydric hypochromic anemia, pellagra, Plummer-Vinson syndrome, chronic dysentery, jejunostomy, intestinal stricture, dibotriocephalus-latus infestation, achlorhydria, steatorrhea⁴⁴ and myxedema.⁴⁵ Manson-Bahr⁴⁴ has reviewed this subject at great length. The high incidence of achlorhydria in almost all these conditions has been frequently commented on.^{3, 4}

Oatway and Middleton,²⁰ in a detailed study, correlated the lingual changes with the gastric acidity, using tongue prints, made on smoked paper that was shellacked, to secure objective detail. Their work indicates that papillary atrophy was rare when normal acidity or hyperacidity was present, and frequent with achlorhydria. This study gives support to the clinical impression that achlorhydria and atrophic glossitis are frequently associated. Hutter, Middleton and Steenbock⁴⁸ produced smoothing of the highly serrated papillae of the tongues of rats kept on a diet deficient in vitamin B complex. Elsom⁴⁹ noted soreness and glossitis in a human subject placed on a diet deficient in the vitamin B complex. This did not clear with thiamine but responded to other factors in the B complex. This fact and the frequent response of glossitis to the various forms of therapy mentioned strongly support the contention that the presence of glossitis is a most valuable clinical sign and indicative that some form of nutritional deficiency is present.

Many workers believe that that appearance of the tongue may mirror the appearance of other portions of the gastrointestinal mucosa. The aphorism, "raw red tongue, raw red gut,"⁴¹ has some objective proof to support it. Spies, Bean and Ashe⁵⁰ reported that pellagrins who were gastroscopied had a mucous membrane of the stomach similar in appearance to the stomatitis in the oral cavity. A patient studied at the Evans Memorial Hospital by Ingelfinger⁵¹ is especially illuminating in this regard. This man, in his late thirties, had an ileostomy of long standing, performed because of intestinal obstruction of benign nature. He developed vitamin B complex deficiency, with a glossitis similar to the type mentioned above. The mucosa of the ileum, which could be readily inspected at the site of the ileostomy, was bright red and smooth and appeared edematous. Following appropriate vitamin therapy, both the glossitis and the injection of the ileum improved; the mucosa of the ileum became pink, and its pattern more prominent. Manson-Bahr⁴⁴ found by sigmoidoscopy that the rectal mucosa was hyperemic in acute sprue associated with glossitis and resembled in a general sense the changes seen on the tongue.

Wandering Rash of Tongue

Wandering rash of the tongue appears to be the accepted term for the not uncommon condition known also as geographic tongue, erythema migrans, exfoliativa areata linguae and numerous other synonyms.^{5, 6, 52} It begins as a faint grey or whitish patch anywhere on the anterior dorsum of the tongue. The epithelium of the filiform papillae over this area desquamates, exposing the smoother red surface of the underlying mucosal layer, the isolated fungiform papillae appearing as shiny, red eminences. Thickened filiform papillae form a whitish border about these atrophic red areas, which are usually oval or circular in outline. These atrophic spots migrate continually but irregularly, the epithelium desquamating at one point and regenerating at another, to form bizarre circinate or geographic patterns. The spots may migrate within hours, days or weeks, may remain fixed for days or years, or may clear completely or return repeatedly at varying intervals for many years. Since only the superficial epithelial layer is involved, symptoms are usually absent, and the patient may not be aware of its presence. Greenbaum⁵³ has described a painful form, which appears to be rare.

Wandering rash of the tongue may be readily confused with the atrophic glossitis of deficiency disease. Yet it appears etiologically unrelated to any of the vitamin deficiencies. The patchy desquamation described by Weisberger¹³ for riboflavin deficiency is histologically different. Rhoads⁵⁴ has not seen a cure of this condition from the use of vitamin B complex therapy. When the atrophic patches are along the lateral aspects of the tongue, it may be readily confused with Moeller's atrophic glossitis, but the frequent presence of pain in the latter condition serves to make their differentiation possible.

Wandering rash is common in children, but may be seen at all ages and may appear periodically or continuously throughout life, with perhaps a tendency to disappear as middle age is reached. Prinz and Greenbaum⁵ consider it a local expression of a constitutional neuropathic anomaly. Thoma⁶ believes that there is some evidence for a hereditary background. No therapy is required in most cases.

Grooved Tongue

Grooved tongue, also known as fissured, furrowed or scrotal tongue, a congenital anomaly present in about 0.5 per cent of the tongues of the human race irrespective of age, is commoner in men and often inherited through the male sex.⁵ The monograph by Prinz and Greenbaum⁵ contains a detailed description of this condition and

**CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITAL**ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor***CASE 28321****PRESENTATION OF CASE**

A fifty-seven-year-old widow was referred to the hospital by her physician because of an upper abdominal mass.

Seven weeks prior to admission, when the patient was examined by her physician because of an upper respiratory infection, a mass was felt in the upper abdomen. When specifically questioned, she recalled vague abdominal discomfort unrelated to her dietary habits. Her appetite had always been good. No bowel habit changes were recalled except for diarrhea on a single day two weeks prior to admission. The stools had been normal in appearance.

The past history was not remarkable except for an operation on the thyroid gland performed one year previously. The menopause occurred seven years before admission. There had been no bleeding since then. During the five months prior to admission, the patient noted ankle swelling in the evening; there was no associated dyspnea or orthopnea.

Physical examination revealed a well-developed, slightly obese woman who was in no discomfort. The pharynx and tonsils were congested. There was slight spasm in the right upper abdomen, and a mass could be felt in this region. The heart and lungs were normal, and the rest of the physical examination was negative.

The temperature was 98.6°F., and the pulse 100. The blood pressure was 120 systolic, 74 diastolic.

The blood was normal. The urine was normal except for 10 to 15 white blood cells per high-power field and a slight growth of *Staphylococcus albus*. The stool was brown and guaiac negative.

A barium enema revealed several diverticulums of the descending colon. A gastrointestinal series and intravenous pyelogram were negative. A Graham test showed no concentration of the dye in the gall bladder. No stones were demonstrated. The abdominal flat film showed a round soft-tissue shadow about 11 cm. in diameter in the right midabdominal field overlying the crest of the ilium and lower pole of the right kidney. Review of these films showed that the soft-tissue

mass was inferior to the liver and produced little pressure on the colon.

On the twelfth day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT R. LINTON: In summary, this fifty-seven-year-old woman apparently had a mass in the right upper quadrant, with very few if any related symptoms. What are the possibilities with a mass in the right upper abdomen? One thinks first of gall-bladder conditions. A second possibility is a tumor of the right portion or hepatic flexure of the colon. A third is a tumor involving the right kidney. Other remote possibilities are gumma of the liver, tumor of the pancreas and echinococcal cyst. Certainly, we have no evidence that the last was present, and we have no laboratory findings to help us out on that diagnosis. Tumor of the head of the pancreas of that size would certainly have produced some signs of biliary obstruction, which were not present. A tumor involving the lower pole of the kidney is apparently ruled out because of the negative pyelogram. The question of hepatic-flexure growth can also be fairly well ruled out, I believe, by the barium enema, which was negative except for the diverticulosis, which I do not believe played any part in this patient's story. The hepatic flexure is known to be hard to visualize by x-ray, but I think we can rely on the report that the barium enema was negative for a lesion in this portion of the colon. In addition, there was a negative guaiac test on the stool.

The question of gall-bladder disease should be seriously considered. I do not believe it is necessary for patients with gall-bladder disease to have many gastrointestinal symptoms. Certainly, this patient had a minimum, if one accepts the story as it is written here.

One other condition that might be considered is a fibroid of the uterus. It is unusual to see fibroids above the pelvis, especially in the right abdomen, but I know that they do occur there. An ovarian cyst should also be thought of. I think these are unlikely, however, in view of the fact that the patient was seven years past the menopause. Before going on any farther with the discussion, I think we might see the x-ray films.

DR. LAURENCE L. ROBBINS: The mass is rather hard to see on these films, but this is its location. It apparently causes a little pressure on the proximal portion of the transverse colon. The mass appears to be homogeneous, and is of soft-tissue density.

DR. LINTON: Should you say that it was above the transverse colon?

DR. ROBBINS: I should say that it was. I think this represents the mass here.

A PHYSICIAN: Is there a kidney film?

DR. ROBBINS: There is a film in which one can see the right kidney, which seems to be all right. The film was taken to show the gall bladder; it shows the right-kidney shadow very clearly, however.

DR. LINTON: The intravenous pyelogram does not show any abnormality?

DR. ROBBINS: It does not show any pressure on the calyces that I can see.

DR. LINTON: It also shows the kidneys very well. The mass as I see it is a rather spherical one. Is that right?

DR. ROBBINS: Yes.

DR. LINTON: It is rather unusual for a gall-bladder shadow. However, it is located in the proper position—under the inferior surface of the liver and pressing the hepatic flexure and transverse colon downward.

One other condition that I had not considered is mesenteric cyst. I do not know any way to rule it in or out, but I think it is a possibility. The mass seems too far lateral on the right side to suggest a pancreatic cyst. I think the differential diagnosis lies between a dilated gall bladder, a hydrops of the gall bladder with a stone impacted in the ampulla and a tumor of the lower pole of the kidney, without evidence of pressure on the kidney; in view of the x-ray film, I must make a diagnosis of hydrops of the gall bladder. The negative Graham test adds support to this diagnosis.

CLINICAL DIAGNOSIS

Hydrops of gall bladder.

DR. LINTON'S DIAGNOSIS

Hydrops of gall bladder, with stone impacted in ampulla.

ANATOMICAL DIAGNOSES

Hydrops of gall bladder.

Acute and chronic cholecystitis.

Cholelithiasis.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This patient was explored, and a very large, greatly dilated gall bladder was found. When it was opened, it contained nearly colorless bile. It showed a number of small white stones. The walls showed both chronic and acute inflammation, and there was one abscess in the wall. It is a little surprising that the patient did not have some evidence of systemic reaction

because there was quite marked infection, as well as mechanical stasis.

DR. LINTON: What was the obstruction due to?

DR. MALLORY: I should have mentioned that a stone was impacted at the mouth of the cystic duct.

CASE 28322

A sixty-year-old man entered the hospital complaining of dysphagia of two weeks' duration.

The patient was well until six months before admission, when he began to feel weak and run down and noticed that he was losing weight. Approximately two months before admission, because of continued weight loss, he consulted his physician, who had a chest plate taken and told the patient that he had tuberculosis. Three weeks later, he entered another hospital; at the time, he had a slight cough productive of white sputum. No tubercle bacilli were found in the sputum on repeated examinations, and a chest plate was said to have been somewhat characteristic of tumor. Two weeks before admission, the patient had a severe paroxysm of coughing and raised about 30 cc. of bright-red blood. This was followed immediately by persistent dysphagia, which increased so that at the end of a week he was able to swallow only small amounts of ice water and subsisted on parenteral fluids. There had been no vomiting, regurgitation or other symptoms referable to the gastrointestinal tract or respiratory system. The patient was transferred to this hospital, and on admission his cough was still productive of about a cupful of white sputum each day. He had lost 60 pounds, and complained of profound weakness.

The patient's father had died at seventy-three of a tumor in the abdomen.

On examination, the patient was extremely emaciated, dehydrated and weak. Examination of the chest showed poor aeration throughout the right lung, with absent signs at the base, more prominent posteriorly, and diminished to absent breath sounds over the upper lobe. There was no apparent shift of the mediastinum, and the left lung was clear. The heart was normal. Abdominal and rectal examinations were negative.

The temperature was 99.2°F., and the pulse and respirations were normal. The blood pressure was 120 systolic, 80 diastolic.

The urine was normal. Examination of the blood showed a red-cell count of 3,500,000 with a hemoglobin of 12.7 gm. (photoelectric-cell technic), and a white-cell count of 52,000 with 93 per cent polymorphonuclears. The nonprotein nitrogen of the blood serum was 16 mg. and the protein 5.1 gm. per 100 cc.; the chloride was 104.2

milliequiv. per liter, and the carbon dioxide combining power 29.9 vol. per cent. A blood Hinton reaction was negative.

X-ray films of the chest showed a large mass in the posterior upper mediastinum that displaced the esophagus and trachea forward. A large portion of this mass was seen to lie in the tracheo-bronchial angle. There was extensive mottled consolidation in the lower portion of the right lung field, which, in the lateral view, was seen to correspond mainly to the lower lobe, with possible involvement of the middle lobe. The chest was large, particularly in the precordial space, and the diaphragm was low.

On admission, attempts to pass stomach tubes of various sizes met with obstruction in the mid-esophagus. A barium swallow the following day showed extrinsic pressure on the esophagus, and a moderate amount of barium passed into the stomach. Following this procedure, the patient was able to take esophageal feedings. The esophagus was dilated with bougies, and he could swallow water and food, nourishment being supplemented by intravenous fluids. Two weeks after admission, the sputum became copious and purulent. X-ray therapy was started, but the first treatment had to be discontinued because of the patient's condition. He rapidly failed, and died on the seventeenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. HELEN S. PITTMAN: The sequence of events in this case is weakness and weight loss, cough and, finally, bleeding after a very severe paroxysm of cough. Immediately after this, the patient had dysphagia, which increased in a week to a point where he could swallow only small amounts of ice water. There had been no symptoms pointing to the gastrointestinal tract until immediately after the severe cough and hemorrhage.

Two months before admission, when the only complaints were weakness and weight loss, a chest plate showed something interpreted as tuberculosis. I believe this was the "extensive mottled consolidation in the lower portion of the right lung field" that was present on our films. The film three weeks later, by which time the patient had a slight cough, was said to have been more characteristic of tumor. I interpret this as referring to the large mass visible in the mediastinum, which either did not show up on the first film (and I think it might easily have been missed on a posteroanterior film) or had increased in size in three weeks.

The severe paroxysm of cough might have been caused by pressure or by aspiration, but it would not have produced 30 cc. of blood unless the act of coughing ruptured something. The dysphagia that followed suggests that there was internal as

well as external bleeding, producing a hematoma that pressed on the esophagus.

On admission, the patient was emaciated and dehydrated. The red-cell count and the protein of 5.1 gm. per 100 cc. are consistent with his malnutrition. The other chemical levels are within the normal range. The white-cell count of 52,000 makes one think at once of leukemia. We are not given a description of the smear, but are told only that there were 93 per cent polymorphonuclears. In the absence of any information about abnormal cells, this may be interpreted as indicating suppuration. Two weeks after admission, the sputum became copious and purulent. This I interpret as drainage of multiple small pulmonary abscesses that, undrained, had been responsible for the leukocytosis. I suppose one should consider the possibility of trauma from the passage of bougies, with subsequent infection, but I shall not do so in view of the elevated white-cell count on admission.

There were apparently two lesions within the chest,—the mass in the mediastinum and the right-lower-lobe disease,—and it is of the utmost importance in arriving at a diagnosis to try to decide which came first. If we accept the sequence as demonstrated by the x-ray films and assume that the intrapulmonary disease came first, we may say that the mass represented mediastinal metastasis or abscess. I have never seen a metastasis like this, and I do not believe the patient was sick enough for this to have been a mediastinal abscess.

It seems reasonable to assume that the mass was the older, even though it was not seen on the first x-ray film. The commonest tumor of the posterior mediastinum is neurofibroma. These tumors frequently arise from the wall of the esophagus but do not invade it, therefore giving external pressure only. The simple cysts of the mediastinum that I have seen have been lower. They usually arise from bronchial epithelium and therefore lie anterior to the esophagus. However, hemorrhage in a cyst with external leak would account for the sequence of bleeding and sudden dysphagia, and must be considered. Leakage from an aneurysm might behave in the same way, but the site of this mass would correspond to the ascending aorta, which was anterior and not posterior; the blood Hinton reaction was negative; finally, although we are given no fluoroscopic note of whether or not the mass pulsed, we know that x-ray treatment was planned, and I think aneurysm, unless nonpulsating because of laminated clot so that the fluoroscopist was misled, may be excluded. Lymphoma must be included in every such differential diagnosis. I see no way to rule it in except by x-ray response. The patient

could not tolerate even one treatment, but I attribute that to his general condition, for there was not time for it to have been reaction to x-ray therapy. An intrathoracic thyroid gland lies anterior, and a dermoid cyst and sarcomas are usually anterior. Carcinoma of this size arising from a bronchus should cause bronchial obstruction and atelectasis, and there were none.

Whatever the nature of the mediastinal mass, we must not forget the process in the right lower lobe. There was poor aeration throughout the right lung, with "absent signs" at the base, whatever that means. That does not help much, for, if the lesions were central, there need have been no characteristic physical signs. Aspiration pneumonia is usually bilateral but may occur on one side, and the right lower lobe is said to be the commonest site. However, it seems unlikely that the patient could have aspirated sufficient food to give this reaction without any conscious dysphagia. We have no information to suggest phlebitis, from which he might have had pulmonary emboli. Spontaneous abscess is usually single rather than multiple.

The patient was weak and run down, and lost weight for almost five months before he had any cough. This is not too uncommon in carcinoma of the bronchus. Infection distal to bronchial carcinoma is almost the rule, although when there is sufficient obstruction to allow infection behind it, there should be a wheeze if one listens for it. Patients with bronchial carcinoma bleed as this man did. Benign adenoma can behave exactly like carcinoma, and the diagnosis can be made only by biopsy. It is my impression, however, that in most cases of adenoma there is complete obstruction, with atelectasis.

As in most tumors, the diagnosis without tissue examination is one of guesswork. I therefore make my guess that the most probable diagnoses were two independent conditions: neurofibroma, probably arising from the esophagus; and primary carcinoma of the right-lower-lobe main bronchus, with abscess formation behind the bronchial obstruction.

CLINICAL DIAGNOSES

Carcinoma of lung, bronchiogenic.
Bronchopneumonia, slight.

DR. PITTMAN'S DIAGNOSES

Neurofibroma, probably arising from esophagus.
Primary carcinoma, right-lower-lobe main bronchus, with abscess formation behind bronchial obstruction.

ANATOMICAL DIAGNOSES

Epidermoid carcinoma, bronchiogenic, of right upper lobe, with extension to esophagus, vertebrae and mediastinal lymph nodes.
Pulmonary abscesses, multiple, right upper lobe.
Empyema, right, massive.
Emaciation.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The contiguity of the upper respiratory and gastrointestinal tracts makes it comparatively easy for a malignant process arising in either to invade the other at a comparatively early stage of its development. Consequently, we see cancers of the lungs with the presenting symptom of dysphagia, and primary cancers of the esophagus in which the first symptom may be cough or hemoptysis. The picture is often further complicated by extensive secondary infection so that one is often faced with a double barreled problem, as Dr. Pittman was in this case and must try first to name the source of the neoplasm and secondly to localize the complicating infection. I do not believe in this case Dr. Pittman received the help from the roentgenologist that she might reasonably have expected. I am quite unable to make the facts determined at autopsy check with their recorded observations.

The primary lesion, as Dr. Pittman predicted was neoplasm, a carcinoma arising in the bronchus to the right upper lobe. It had grown downward along the right primary bronchus which was almost completely occluded. The tumor occupied approximately half the upper lobe and the lungs peripheral to it contained innumerable abscesses, one of them measuring 2 cm. in diameter. In contrast, the right lower lobe where the radiologist found evidence of extensive consolidation showed practically nothing but minimal acute terminal bronchopneumonia at the time of autopsy. There was also on this right side an extensive empyema consisting of nearly 2000 cc. of very turbid foul-smelling fluid. This unquestionably was a terminal event, and there was no evidence pointing to it in the recorded summary. The tumor had invaded extensively the posterior mediastinum and, in fact, had extended deeply into the two upper thoracic vertebrae. It had grown through the wall of the esophagus, and two intraluminal tumor masses were present to account for the esophageal obstruction. The mucosa over these was not ulcerated, however. Consequently the picture was not unlike that seen with an intramural leiomyoma or neurofibroma of the esophagus, as Dr. Pittman suggested. No distant metastases were found.

WAR AND VENEREAL DISEASE

THIS country is at war, and venereal disease is on the increase. Just when the national campaign against syphilis and gonorrhea was beginning to bear fruit, there has been an upward turn in the incidence curve of these diseases, chiefly owing to an increase of the venereal-disease rate in the armed services. Every possible effort is being made to educate the men to avoid these diseases, and healthy activities to employ their spare time are provided. The Army and Navy Medical Corps and the United States Public Health Service are expanding their personnel as rapidly as possible to cope with the situation. Two outstanding problems in this field require the co-operation of practicing physicians.

The first concerns the situation in cities and towns near large encampments of men. The

efficient handling of prostitution and of syphilis and gonorrhea in the civil population requires the closest co-operation of the military and civil authorities and the physicians of the particular district. Provisions for the detection of new and old cases, for their quarantine and for adequate treatment and follow-up are taxing the resources of many communities. Somehow or other, the job must be done, to avoid the noneffectiveness that existed in the last war.

The second problem concerns the selectees who are excluded from military service because of evidence of syphilis or gonorrhea. Some of these 45,000 men from the first million selectees could undoubtedly be rendered fit for service, but they must be followed up and treated. Elsewhere in this issue of the *Journal*, Dr. Vonderlehr indicates that only half these men have been brought to treatment and that many communities have done comparatively little in the way of finding them. He points out, "If this opportunity is lost, . . . it will constitute one of the greatest public-health and medical failures in the history of the United States."

THE HERITAGE OF CONNECTICUT MEDICINE

THE Connecticut State Medical Society celebrated its sesquicentennial this year in June at Wesleyan University, with an appropriate program of general and historical interest and by the publication of *The Heritage of Connecticut Medicine*,* a volume containing a history of early medicine in the state and numerous essays on famous Connecticut physicians—William Beaumont, Horace Wells and the Doctors Welch—and the advances in medical teaching and practice, public health, psychiatry, physiology, surgery and tuberculosis as they have developed in Connecticut. Both the meeting and the book are outstanding contributions; Connecticut, with its first meeting of the state medical society in 1792, has indeed set an example that other states might well follow.

**The Heritage of Connecticut Medicine*. By various authors. Edited by Herbert Thoms, M.D. 223 pp. New Haven, Connecticut: privately printed for the Connecticut State Medical Society, 1912.

The beginnings of organized medicine in Connecticut go back well into the eighteenth century, since an attempt was made to obtain a charter as early as 1763. This failed but, in 1784, the New Haven County Medical Society was founded, and its famous transactions, *Cases and Observations*, printed in 1788, was the first medical publication in this country. It was not until October 9, 1792, however, that thirty-six practitioners of medicine gathered in the Court House in Middletown for the first meeting of the Connecticut State Medical Society. The names of these physicians have a familiar ring in New England medicine,—Hubbard, Munson, Potter, Tudor, Flagg, Mather, Coit, Clark, Lord, Woodward and others,—and not a few men bearing the same surnames serve Connecticut and the other New England states today.

Thus, the fourth state medical society to be established in America came into being; its past performance is great, and its future can be no less. Many should read, with pleasure and profit, the history of the illustrious past of this state medical society, and of the lives of the physicians who made it. The volume is worthy of the heritage presented on its pages, and shows that Connecticut doctors of our day have thoughtfully and wisely evaluated the work of their colleagues of the past.

MEDICAL EPONYM

PURKINJE FIBERS

These fibers were described by Professor Johann Evangelista von Purkinje (1787–1869), of Prague, in an article "Mikroskopisch-neurologische Beobachtungen [Microscopic-neurologic Observations]," published in the *Archiv für Anatomie, Physiologie und Wissenschaftliche Medizin* (681: 281–295, 1845). A portion of the translation follows:

On the inner walls of the ventricles of the sheep's heart, I observed, first with the naked eye, a network of gray, flat, gelatinous threads immediately beneath the serous membrane. . . . On microscopic examination, I found these threads to be entirely made up of granules. . . . Inside each granule, there were one or two nuclei without any spherical envelope such as is seen in true ganglion cells. The fibers were formed of cross rows of five or ten of these granules, arranged serially in bundles.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

CASE HISTORY: FATAL ECLAMPSIA

A thirty-eight-year-old multipara had had adequate though unintelligent care during her ninth pregnancy. Her previous pregnancies had been normal, and the past history was irrelevant. At the beginning of this pregnancy, the blood pressure was 150 systolic, 90 diastolic; the systolic blood pressure rose to 170 during the last two months. The patient had been seen every two weeks from the third month of pregnancy, and the urine was reported to be normal. In the last month of pregnancy, she was seized with a sharp pain under the right shoulder, for which she was given $\frac{1}{4}$ gr. of morphine. Two or three hours later, she began to flow and had a convulsion, which was the first of several that occurred before she entered the hospital. The day after entry, she delivered herself of a stillborn baby. There was no post-partum hemorrhage, but she had one convulsion after the birth of the child. Examination of the blood showed a steadily rising nonprotein nitrogen; almost complete anuria developed, which resulted in death ten days after delivery.

Comment. This death was undoubtedly an unnecessary obstetric fatality. Any patient who starts a pregnancy with a systolic blood pressure of 150 that reaches 170 at seven months and continues at that elevation should probably never be allowed to go to term. After the convulsion, nothing could have been done that was not done to ensure recovery. Induction any time after the beginning of the last month, either by rupture of the membranes or by the use of a Voorhees bag,—preferably the former,—would have saved the mother's life and probably prevented the death of the baby.

Routine visits on patients of this sort do not necessarily mean intelligent obstetrics. This patient had routine care; it was not, however, intelligent.

DEATHS

BRYANT—ALICE G. BRYANT, M.D., of Boston, died July 25. She was in her eighty-first year.

Born in Boston, Dr. Bryant received her degree from Woman's Medical College of the New York Infirmary for Women and Children in 1890. She was associated with Vincent Memorial Hospital, New England Hospital for Women and Children and New England Deaconess Hospital. She was a member of the American Academy of Ophthalmology and Oto-Laryngology, and a fellow of the Massachusetts Medical Society and the American Medical Association.

BURNETT—N LOWE BURNETT, M.D. of Cambridge, died July 20. He was in his fifty sixth year.

A native of Springfield, Dr. Burnett received his degree from Queen's University Faculty of Medicine in 1915. He was president of the Bay State Medical Association, and a former member of the Massachusetts Medical Society and the American Medical Association.

His widow, three sons and a daughter survive him.

FROTHINGHAM—CHARLES B. FROTHINGHAM, M.D., of Lynn, died May 28. He was in his eighty fifth year.

Dr. Frothingham received his degree from Dartmouth Medical School in 1892. For many years, he was city physician in Lynn and a member of the school committee. He was a former member of the Massachusetts Medical Society.

GLIDDEN—HOWARD K. GLIDDEN, M.D., of Swampscott, died May 30. He was in his sixty eighth year.

Dr. Glidden was a former member of the Swampscott Board of Health, and a former member of the Massachusetts Medical Society and the American Medical Association.

MORSE—ALMON G. MORSE, M.D., of Hingham, died July 27. He was in his seventy fifth year.

A native of Watertown, Dr. Morse received his degree from Harvard Medical School in 1894. He served as house officer, assistant surgeon and surgeon in chief at the Massachusetts Eye and Ear Infirmary. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, two sons and a daughter survive him.

STACK—CHARLES F. STACK, M.D., of Hyde Park, died April 3. He was in his seventy second year.

Born in Hyde Park, Dr. Stack received his degree from Harvard Medical School in 1898. He served his internship at Boston City Hospital and did postgraduate study in Europe. He was a member of the Massachusetts Medical Society and the American Medical Association.

A son and a daughter survive him.

WAR ACTIVITIES

CIVILIAN DEFENSE

The following memorandum was recently issued by the Office of Civilian Defense, Washington, D. C. regarding the relation of emergency medical services to industrial plants.

* * *

The primary responsibility for the protection of industrial plants rests on the operators, owners, and local and state governments. The War and Navy departments have included in their protective program the responsibility for surveying and recommending protection within certain civilian manufacturing plants engaged in the production of war materials, as well as for plants owned and operated by these departments. The emergency medical services provided in these plants and in all other plants should be closely integrated with the local emergency medical services. The War and Navy departments have requested all civilian manufacturing plants having important war contracts to co-operate with the local emergency medical service of the United States Office of Civilian Defense. All local chiefs of emergency medical services should be prepared to co-operate with the man-

agements of plants having important War and Navy contracts whenever requested, by responsible officials within the plants, to do so.

All industrial plants are expected to provide medical services and first aid equipment within the plant for the care of the injured. In the event of enemy action directed against such industrial plants, the physicians, nurses and first aid detachments within the plants may be inadequate to care for the serious injuries produced by high explosives or incendiaries. It is the recommendation of the Office of Civilian Defense that each industrial plant, in addition to providing its own medical staff and first aid equipment, should plan in collaboration with the chief of emergency medical services of the locality for services of ambulances, when needed, available beds at one or more hospitals, to which the severe casualties may be transported, the establishment of a casualty station of the emergency medical service within a short distance of the plant, and the services of emergency medical field units, if needed to supplement the plant medical service during an emergency.

In view of the fact that enemy action against industrial plants may be coincidental with widespread damage to the adjacent community, the mobilization of civilian medical resources during an emergency will be accomplished through the commander of the citizens' defense corps.

If a plant is miles from a hospital and there is, therefore, a possibility that the injured may be obliged to remain at the casualty station for many hours before being transferred to the hospital, the casualty station should be larger than the average for a given number of employees and be adequately equipped. It must have cots, blankets, water and heating facilities, and be equipped at least with the emergency medical supplies.

MISCELLANY

NOTES

Thirty three appointments to the teaching and research staffs of the Harvard Medical School, effective July 1, were recently announced by Harvard University as follows:

Assistants in surgery Robert K. Brown, of Colorado Springs, Colorado, M.D. Harvard '37, Richard C. Durant, of Great Barrington, Massachusetts, M.D. Harvard '34, Howard A. Frank, of Woodmere, Long Island, New York, M.D. New York University '37, John J. Lowrey, of Honolulu, M.D. Harvard '40, Donald D. Matson, of Altadena, California, M.D. Harvard '39, Arnold Porter, of Providence, Rhode Island, M.D. Harvard '40, Frank R. Pierce, of Gardner, Massachusetts, M.D. Harvard '34, Carter R. Rowe, of Fredericksburg, Virginia, M.D. Harvard '33, Eric R. Sundersen of Boston, M.D. Harvard '37, Neal W. Swinton, of Waban, Massachusetts, M.D. University of Michigan '29, and Lester P. K. Yee, of Honolulu, M.D. Harvard '37.

Assistants in medicine Howard E. Allen, of Salt Lake City, M.D. Pennsylvania '38, and Samuel Stearns, of Dorchester, Massachusetts, M.D. University of Michigan '39.

Research fellows in medicine Grosvenor W. Bissell, of Buffalo, New York, M.D. University of Buffalo '39, William C. Bridges, of Tacoma, Washington, M.D. Yale '40, Harry A. Feldman, of Newark, New Jersey, M.D. George Washington University '39, Seymour S. Kety, of Philadelphia, M.D. Pennsylvania '40, Charles R. Park, of Garrison, Maryland, M.D. Johns Hopkins '41, and Edward

C. Reifstein, Jr., of Syracuse, New York, M.D. Syracuse '34.

Assistants in gynecology: John R. Barker, of Waban, Massachusetts, M.D. Tufts '31; and Charles L. Sullivan, of Brookline, Massachusetts, M.D. Boston University '35.

Teaching fellows in bacteriology and immunology: Charles A. Macgregor, of Rumford, Maine, M.D. Harvard '42; and James H. Strauch, of Canton, Ohio, M.D. Harvard '42.

Instructors in nutrition: David M. Hegsted, of Chicago, Ph.D. Wisconsin '40; and John M. McKibbin, of Madison, Wisconsin, Ph.D. Wisconsin '42.

Visiting lecturer on anatomy: William C. Young of New Haven, Connecticut, Ph.D. University of Chicago '27.

Instructor in anatomy: Richard J. Blandau, of Providence, Rhode Island, Ph.D. Brown '39.

Teaching fellow in anatomy: Macelyn V. Anders, of Marietta, Ohio, S.M. Brown '42.

Assistant in bacteriology and immunology: John B. Hamblet, of Lowell, Massachusetts, M.D. McGill '40.

Assistant in roentgenology: Lloyd E. Hawes, of West Somerville, Massachusetts, M.D. Harvard '37.

Assistant in psychiatry: James E. Roy, of Worcester, Massachusetts, M.D. Harvard '39.

Assistant in neurology: Frederick G. Woodson, of University, Virginia, M.D. University of Virginia '38.

Instructor in pathology: Clinton Van Z. Hawn, of Albany, New York, M.D. Harvard '41.

Dr. Harris P. Mosher, professor of laryngology and otology, emeritus, at Harvard Medical School, was awarded an honorary degree at the recent commencement exercises of Jefferson College, Philadelphia.

Dr. Reginald Fitz, lecturer on the history of medicine and assistant to the dean, Harvard Medical School, recently delivered the commencement address at the University of Vermont College of Medicine.

Dr. Frederic A. Gibbs, of Boston, was recently elected secretary-treasurer of the American Branch of the International League against Epilepsy.

Fifteen members of the first-year class at Tufts College Medical School were recently awarded Charles Hayden Memorial Scholarships of \$250 each. Dr. Cadis Phipps, chairman of the scholarship committee and head of the Department of Medicine, distributed certificates denoting the awards. The recipients were as follows: John J. Carty, of Jamaica Plain; Francis L. Colpoys, Jr., of Brighton; Harvey H. Corman, of Dorchester; Francis X. Mack, of Milton; Edward Martin, Jr., of Milton; John A. McGowan, of Medford; John C. McLaughlin, of Brookline; Willard Nicholl, of Needham; Emil Pagliarulo, of East Boston; Vincent P. Perlo, of Brookline; Harold S. Rubin, of Swampscott; Robert J. Scannell, of Brighton; Stuart A. Silliker, of Cambridge; Richard E. Stiles, of Roslindale; and Francis A. D'Ambrosia, of Boston.

CORRESPONDENCE

LEGAL ASPECTS OF FIRST AID

To the Editor: I have been greatly interested in the work that is being done in training groups of laymen in first aid. But neither in the courses for air-raid wardens nor special police, which I have attended, in the course for physicians given by the Massachusetts Committee on

Public Safety nor in any publication have I seen any reference to the medicolegal aspect of first aid.

These men and women, who are giving their time and energy to prepare for the emergencies that seem more inevitable day by day, deserve nothing but commendation. They are doing a fine piece of work, of which the public, including the medical profession, knows too little. If, as a result of their efforts to care for air-raid victims, they are to incur the risk of becoming defendants in lawsuits, brought by disgruntled "victims" whom they have attended, the fact should be known, so that they may be informed concerning both the extent of the risk and the means at their disposal for avoiding such liability or of meeting it when it comes. Physicians know that it is idle to rely on the gratitude or sportsmanship of patients for protection from lawsuits, and it is not likely that these laymen would find themselves in any better position in the event of some unforeseen catastrophe.

CHARLES E. WELLS, M.D.

15 Union Street
Randolph, Massachusetts

* * *

Dr. Wells was referred to an article, "Legal Aspects of First Aid by Lay People," in the June, 1942, issue of *Minnesota Medicine*. Since the laws governing such actions vary from state to state, the *Journal* will attempt to obtain an opinion concerning the legal aspects of first-aid care in Massachusetts. — Ed.

REPORTS OF MEETINGS

NEW ENGLAND PEDIATRIC SOCIETY

A regular meeting of the New England Pediatric Society, with Dr. Warren R. Sisson presiding, was held at Longwood Towers on March 25.

The first speaker was Dr. Richard M. Smith, whose talk was entitled "Protection of Children in Wartime." Definite problems are precipitated in the danger zones of the seaboard and areas near defense industries or military targets. It has been generally agreed that the registering of all children in such areas is advisable and feasible, but although the Office of Civilian Defense recognizes these facts the priorities board states that no metal is available for tags. And to be effective, registration must be done on a national scale. In evacuation of any of these zones, children are the first priority group, and the plans for their removal in an emergency are already under way in most communities. The only question that arises is the feasibility of carrying out such evacuation prior to the expected incident.

The problem of general immunization against communicable diseases is always present. Proclamations have been issued making smallpox and diphtheria prophylaxis mandatory, but it is generally believed that at least tetanus should be added to this list. The camp movement should be extended, not only to provide "war vacations" but also to afford much-needed experience in mass evacuations.

The psychologic reactions of children to war are multiple and complicated, and by no means insignificant. Even toddlers feel the insecurity and actually experience fear. The problem in older children and adolescents is equally acute, and may be associated with even more serious consequences. The number of delinquencies and misdemeanors rises sharply, and such a possibility is being given the greatest attention in this country, following the sad experiences of England early in the war. This problem,

as well as others, is greatly accentuated by the rapid growth of such communities as newly created defense centers. Some areas have already experienced 1000 per cent increases in population. This introduces problems in housing and sanitation and all the difficulties entailed in quarters composed of trailers and improvised shacks. The need for medical care far outstrips the ability of the doctors to handle it. School facilities, in both material and personnel, soon become greatly overburdened, and it is freely predicted that all rural schoolteachers who are not already in war industry soon will be. Child labor again rears its head and the percentage of children employed is already rising sharply in many communities. Home life is disintegrating with the increase of men in various branches of the armed forces and of mothers in war industries. The absence of men leads to a great sense of insecurity. These facts have heightened interest in day care for children. Another potent factor, of course, is the high percentage of early divorces following hasty war marriages, which leave children essentially orphans.

In general, a concerted effort should be made to maintain the standards of child health so far as possible, with concessions only on a temporary basis if absolutely necessary and, then, with the least harm to the children. Furthermore, new and emergency methods should be developed to meet the particular situations arising from the war.

The second speaker of the evening was Dr. Joseph Stokes of Philadelphia, whose subject was "Communicable Diseases in Army Camps." This was essentially a report of the work of the Board of Communicable Diseases, especially regarding measles and mumps. Although there is a great need in wartime for control of these conditions, an ideal opportunity for investigation is also afforded. During the last war, there were 98,000 cases of measles with about 40 per cent mortality, and in the 40,000 cases of mumps, the incidence of orchitis varied from 5 to 40 per cent.

In the treatment and prophylaxis of measles, there is a crying need for large amounts of placental extract or pooled immune serum. One advantage of Cohn's albumin in the treatment of shock is the saving of large quantities of globulin, which may be useful in this role. Experiments are now in progress to test the efficacy of this fraction against some viruses, but more study is necessary. At the Army Medical School, there is now a central collecting depot for immune serum. Passive immunity is obviously of no use except on hospital wards for it lasts only two or three weeks. It is practical, however, when non-immune patients are on a ward after exposure or are being sent on active duty following a measles outbreak in camp. The sulfonamides are being employed in alternate cases of measles for investigative purposes.

Since the virus of measles has been isolated from the brain of a person dying of measles encephalitis, it is considered advisable to treat such patients early with massive doses of convalescent serum. Similar therapy, consisting of as much as 150 to 200 cc in children, may modify or even prevent the rash of measles if inaugurated as soon as Koplik spots are noted. To decrease the ever-present danger of cross infections, the use of propylene glycol vapor and ultraviolet light is being tried in camps.

The only study so far on mumps has been the treatment of alternate patients with convalescent serum to determine its effect on the incidence of orchitis. The use of serum in one series and of incision in another, on alternate cases, is being contemplated. In mumps encephali-

tis, the virus may also be involved, but the treatment of alternate cases is probably impracticable because of the small number of cases. So far, there have been more cases of mumps than measles, but both diseases have been relatively low in incidence. As a preliminary report, there is a favorable feeling toward the effect of serum on orchitis. The question that there may be some synergistic action of the gonococcus on mumps orchitis has led to the proposal of sulfonamide treatment.

One of the most important interim investigations on measles virus concerns the value of active immunization. In 1935, this virus was first grown on the chick embryo but there were no studies on transmission in man or monkey until Plotz passed it in successive steps from the embryo to monkeys and back. The virus could be obtained from both the nose and the blood. Shafer et al. exposed human subjects to measles virus following immunization with virus attenuated on chick embryos. Children and monkeys injected with the latter material develop Koplik spots, neutrophilopenia and only rare skin eruptions, which are of a mild nature. Although there is some fever the malaise is not comparable to that of the usual case, and cough is rare. The resulting disease is even less severe than the attenuated normal disease or that modified by convalescent serum. Of 217 children inoculated with this attenuated virus, only 10 per cent on subsequent exposure contracted moderately severe measles, whereas in the rest the disease was mild or minimal or did not occur. The virus was administered intranasally and intradermally with essentially no difference in results, with the possible exception that intranasal administration seemed to cause some Koplik spots. In another series in which 43 nonimmune subjects were exposed to measles, 25 of the 36 untreated ones developed measles, whereas none of the 7 immunized persons developed the disease. A challenge inoculation of blood from patients with active measles into 15 such actively immunized children resulted in only 5 cases of the disease 7 of which were modified.

Many years of study are necessary to settle the efficacy of this attenuated virus. There is need for better titration methods, monkey neutralization being the only present means of standardization. Whether to use this in the army is still debatable, since there is still some suggestion that the virus may be reactivated by human passage.

GREATER BOSTON MEDICAL SOCIETY

At a regular meeting of the Greater Boston Medical Society held at the Beth Israel Hospital on April 7, Dr. Samuel Silbert discussed "Recent Advances in the Treatment of Peripheral Vascular Disease."

As standard therapy for peripheral obliterative arterial disease the most important single measure is the absolute abstinence from the use of tobacco. Hypertonic saline solution intravenously was employed in 517 cases of thromboangitis obliterans, 96 per cent of which, when once cured, remained asymptomatic for two to eighteen years if smoking was discontinued. It has been concluded, therefore, that tobacco causes thromboangitis obliterans and that treatment affords excellent results if smoking is stopped.

For the relief of pain, the results have been somewhat less striking. Typhoid vaccine has resulted favorably in many cases, but may be dangerous. Five million bacteria are administered in the first dose, and double that amount at each subsequent injection. This form of therapy is not employed in patients over sixty years of age or when the temperature is more than 101°F. Division of the

sensory nerves of the foot was advocated early in the study of the condition, but should properly be reserved for cases not controlled by the usual sedatives or foreign-protein injections, and also only if there is an intractable ulcer. Otherwise, gangrene may ensue. Nerve block has now superseded division, if either is indicated.

Many methods have been suggested to increase the collateral circulation. Since 1922, at Mount Sinai Hospital in New York City, hypertonic saline solution has been routinely injected in 800 obliterative cases. During that period, major amputations have decreased from 62 to 7 per cent. Although the strict adherence to the no-tobacco rule has undoubtedly favorably influenced these statistics, the percentage of amputations is still much smaller than that at other large clinics. This is not claimed as a specific form of therapy, and it may be employed in arteriosclerotic cases. It should be avoided, however, in patients over sixty-five years of age, in cardiac patients and in nephritic patients. Sympathectomy, which was the result of an astute side observation during operations for spastic paralysis, has been employed in increasingly larger series of cases. This operation removes the normal sympathetic vasoconstrictor activity and, in many cases, increases the temperature and the circulation in the affected extremity. However, Dr. Silbert claims no improvement in walking by decrease of the claudication. He has observed no remarkable change in temperature in the muscles on sacral block, spinal anesthesia or sympathectomy. It is concluded that the circulation is not equally increased in all tissues and that this method is adequate for healing indolent ulcers but not for decreasing claudication. On the other hand, the administration of 300 cc. of 5 per cent saline increased the temperature in all tissues of the extremity. A third general method of increasing collateral circulation is the use of venous stasis of some sort. This also is advantageous only in healing stubborn ulcers. This work resulted from war surgery, which demonstrated that if an artery had to be ligated or sacrificed, the limb was much less apt to develop gangrene if the accompanying vein was divided. It allows some nutrition of the otherwise starved tissues. The three commonest methods of accomplishing venous stasis are: the pavex boot, which rhythmically changes the pressure from -80 to +20 mm.; intermittent venous occlusion, which can be conveniently carried out with an ordinary blood-pressure cuff; and the Sanders oscillating bed, which rhythmically changes the position of the lower extremities in relation to the rest of the body.

Dr. Silbert stated that, at his clinic, varicose veins of the leg are now treated by injection rather than by division of the lower branches, an original high saphenectomy having been carried out.

One of the most striking and highly publicized recent advances is that of the employment of cold in peripheral vascular disease. The initial use of warmth in vascular occlusion is now definitely outmoded. Heat not only increases the circulation to a part but also increases the tissue metabolism and oxygen demand. But when the vessels are unable to respond by vasodilatation and the metabolism increases, the tissues merely have their anoxia accentuated. Local heat in proper amounts, however, is beneficial, and a maintenance of a temperature of 95°F., regulated with a thermostat, is now being employed in the chronic stages of vascular disease. In a rapid decrease of blood flow, such as occurs in embolism, cold in the form of ice bags should be immediately applied to the part. Cold has never been observed to do harm when properly used. Later, mild heat should be applied to increase the collateral circulation. Cold may also be used

advantageously in many cases as a temporary expedient to allay the pain of sudden vascular occlusion.

Another recent advance is the use of heparin to decrease a thrombotic tendency. Derangement of this tendency causes a great increase in surgical mortality, and the management is complicated by the fact that the emboli and thromboses may be multiple, since one is dealing with a tendency. In fact, thromboses cause 6 per cent of all surgical deaths. The proper use of heparin costs ten to fifteen dollars a day for the necessary 250 to 350 mg. It is usually best administered by the continuous intravenous route in physiologic saline solution. It prolongs the coagulation time, but to a variable degree in different people and in the same person at different times. It is used clinically to prevent postoperative venous thrombosis and arterial thrombosis following embolectomy, accidents and so forth, and in the treatment of pulmonary emboli postoperatively and post partum, to aid thrombophlebitis and to decrease central retinal and coronary thrombosis.

Statistics at the Mayo Clinic indicate that 0.7 per cent of all operations, 1.6 per cent of laparotomies and 2.7 per cent of pelvic operations develop thromboses postoperatively. On that basis, Murray, in Toronto, should have had four thromboses in his 400 cases in which he used heparin routinely postoperatively, but there were none. Dr. Silbert is of the opinion that emboli are not apt to occur when swelling or other inflammatory signs accompany the thrombosis. Heparin may be especially helpful in preventing subsequent emboli in a person who has had a nonfatal one. This substance is far too expensive for general use, and the need for some reasonably priced anticoagulant is evident. A possible solution to this dilemma may be Dicoumarin, a compound discovered and synthesized in 1941 but not as yet commercially available. This substance is effective orally and is administered in doses of 50 to 200 mg. about every two days. The coagulability of the blood is usually not affected for several days, and heparin may be temporarily used at first. The effect also persists for several days after cessation of therapy. The incidence of hemorrhage has been greater than that with heparin at the New York hospitals. Treatment of this complication is by repeated blood transfusions. Prothrombin times should be closely followed, needless to say.

There have been promising developments in nonobliterative arterial disease. In Raynaud's disease, Smithwick's modified preganglionic sympathectomy seems to offer hope of relief. Spiegel considered Raynaud's disease a general metabolic disorder and has shown striking results with the use of diets high in vitamin B. This, of course, cannot affect the irreversible changes of associated scleroderma. Some improvement has been claimed following the use of dihydrotachysterol.

Dr. John Homans opened the discussion by offering some views of one of the Boston schools of thought. Hypertonic saline solution has shown no such striking results, whether because of insufficient intensity or duration of treatment. It has been claimed that no increase of circulation can be demonstrated following its use. The Massachusetts General Hospital group claim improvement by a properly executed sympathectomy in any arterial disease, but Dr. Homans agrees that only limited cases are benefited. Tobacco deprivation is undeniably the best of all treatments for thromboangiitis obliterans. The prevalent fungous infections of the feet, however, should be intensively treated, for they may not only complicate but even have some etiologic role in this condition. Complete agreement was voiced with the speaker's opinions

on the use of heat and cold, except in cases of thrombosis, in which Dr Homans believes in moderate heat in an attempt to increase the circulation. He is frankly scared by the not infrequent occurrence of deep and wandering thrombophlebitis following even the gradual and careful withdrawal of heparin. He does not accept Murray's statistics.

Dr E. Everett O'Neil was not sure of the results with hypertonic saline solution. However, sympathectomy is the quickest and most permanent method of increasing the vascular bed in the greatest number of patients in his hands. There is enough spastic element even in the most characteristic obliterative disease to warrant surgical denervation. Twenty-eight per cent of 40 patients had relief of intermittent claudication following sympathectomy. Cold certainly does symptomatically improve both acute and chronic obliterative arterial disease. Refrigeration and the application of a tourniquet have been followed by amputation in two to ten hours, with a great decrease in the amount of shock, bacterial activity and pain. This has been entirely a poor risk group in whom the mortality has been thus lowered from 100 to 50 per cent, largely because of the decreased shock and lack of anesthesia. These mortality data are almost as good as those from many clinics with selected cases. As for heparin and Dicoumarin, he would rather use femoral ligation if the thrombosis can be located. It is no longer necessary except when the site of the thrombosis is hidden. Besides the slowness of its effects, hemorrhagic reactions of Dicoumarin may not respond to transfusions.

Dr John Sears congratulated Dr Silbert on being able to enforce his no smoking rule so successfully. He has been impressed by the number of patients in Dr Silbert's clinic who have open lesions but no pain. One interesting group at the Beth Israel Hospital are the patients with definitely proved thromboangitis, who are now "burned out" and are asymptomatic despite their continued smoking. Since August, 1939, division of the femoral or iliac vein has been immediately carried out as soon as the diagnosis of a deep thrombosis is made. Heparin and Dicoumarin are considered expensive and dangerous.

In conclusion, Dr Silbert emphasized the fact that tobacco is the one proved factor in thromboangitis obliterans. Ice bags should be used only for pain, and the extent of their use controlled by the patients' reactions. This does not preclude the use of immediate embolectomy or vein division if the indications are clear. Heparin withdrawal is admitted to entail definite dangers. Sympathectomy may benefit partly by its psychic effects.

BOOK REVIEWS

The Retina. The anatomy and the histology of the retina in man, ape and monkey including the consideration of visual functions, the history of physiological optics and the histological laboratory technique. By S. L. Polyak, M.D. A fiftieth anniversary publication of the University of Chicago Press. 4th, cloth, 729 pp., with 100 illustrations. Chicago: The University of Chicago Press, 1941. \$10.00.

Nine years of original research in the primate retina and visual pathways are recorded in this volume, whose counterpart, "The Visual Pathway," is now in preparation by the same author.

Three fifths of the book is devoted to a discussion in five sections of methods of investigation, history of visual structure and function from early Greek and Arab times down through European studies to the present time, study of the minute structure of the retina, and an interpretation of function in terms of structure, especially of the

neuroepithelium, the conducting fibers and the synapse. Two fifths of the text is devoted to a general outline, to one hundred full page illustrations amply labeled, to one hundred and twenty nine pages of bibliography and to a full index of contents.

This work must be read to be appreciated, and as an authoritative and stimulating work it should have its place in the working library of every neurophysiologist, neuropathologist, neurologist and ophthalmologist, especially if such a specialist is engaged in research work or teaching. It is one of the outstanding books of the year in the field of ophthalmology.

Hugh Young. A surgeon's autobiography. 8^{vo}, cloth, 567 pp., with 91 figures and 18 portraits. New York: Harcourt, Brace and Company, 1940. \$5.00.

This autobiography covers seventy years of the striking and somewhat unusual career of a urologist, one of the better known physicians in recent American medicine. An unusual feature of the volume is the inclusion of details of the author's medical work, a section covering about one fifth of the whole book. Over one hundred pages are virtually a textbook of urology, with numerous drawings of surgical operations and urologic instruments. Since Dr. Young was primarily a surgeon, who pioneered in his specialty, he gives the complete story. He justifies his decision in the preface, by writing "Urology was too important a part of my life to be omitted. That would be sacrificing the true picture." He elected to tell the most important happenings in his medical career, exactly as he would narrate any other event of interest to him. The anatomic and surgical drawings are remarkably clear and labeled so that they can be viewed with understanding by an intelligent layman.

The rest of the story is somewhat less striking. His early life in Texas and at the University of Virginia is well told, but physicians will welcome most his notes on the early days of the Johns Hopkins Hospital, with fleeting pictures of Finney, Osler, Welch, Flexner and, particularly, Halsted. There are no deep characterizations, only touches, leaving one with a desire for more.

Young's later life was one of great activity—in the AEF and in Maryland, where he was energetic in fostering legislation for the control of tuberculosis and the care of the insane. He traveled abroad extensively, and many chapters are devoted to his trips and his interest in sports.

In general, the book is interesting, for the author led a colorful life. There is, however, in the reviewer's opinion, little brilliance and some bad taste. Through it all runs the fixed purpose of advancing urology, and to those particularly associated with this special field of surgery, the book will serve as a milestone in that advance. To others, the book offers some basic material to round out the history of medicine in America.

Subacute Bacterial Endocarditis. By Emanuel Libman, M.D., and Charles K. Friedberg, M.D. Edited by Henry A. Christian, M.D., LL.D., Sc.D. (hon.), F.A.C.P., F.R.C.P. (Can., hon.). Reprinted from *Oxford Leaf Medicine*. 8^{vo}, cloth, 108 pp., with 19 illustrations. London: Oxford University Press, 1941. \$2.75.

When a physician makes a diagnosis of subacute bacterial endocarditis, he realizes that, at the moment, there is little he can do to help the patient. In view of the rapid advances, however, that have been made by modern chemotherapy, he always looks forward to the time

when some really effective form of therapy for this disease will be devised. And, at such a time, he must be able to recognize the disease in its early stages, when the vegetations are small and before extensive and irremediable structural damage to the tissues has occurred. Consequently, it is gratifying indeed to have this excellent monograph. With the mastering of most of the facts of this book, a physician should find little difficulty in making an early diagnosis. Furthermore, the authors will bolster the morale of the physician, since they state that about 4 per cent of all known cases have a favorable result owing to spontaneous recovery.

This book will also enable the physician to develop a critical estimate of the current literature on the subject. The monograph covers the disease thoroughly, for it is written by well-known clinicians who are keen observers. It also reveals the authority that comes from a wide personal experience, since Dr. Libman himself has personally observed at least 1000 cases from 1899 to 1930.

To review this monograph fully would require a brief summary of every page, because the work is saturated with facts. The bibliography is complete and up to date.

This study should be of value to every clinician. It is also a model for one to follow in the writing of a medical monograph.

Synopsis of the Preparation and Aftercare of Surgical Patients. By Hugh C. Ilgenfritz, M.D., and Rawley M. Penick, Jr., M.D. With a foreword by Urban Maes, M.D., D.Sc. 12°, cloth, 532 pp., with 55 illustrations. St. Louis: The C. V. Mosby Company, 1941. \$5.00.

The subject of preoperative and postoperative care was formerly included in the introductory chapters of volumes on surgery. This minor emphasis was in large part responsible for the aphorism that "the operation was successful, but the patient died." The increasing interest in the care of the patient before and after operation is in large part responsible for the reduction in surgical mortality.

This volume is unusually compact, and its size belies the wealth of information that it contains. The opening chapters are devoted to such general considerations as fluid and electrolyte balance. The major and minor complications of surgery are considered in some detail. In addition to the treatment of these conditions, the authors include prophylactic measures that can be taken for their prevention. Finally, there are problems of care peculiar to biliary, thyroid, colonic and other types of surgery.

The authors are to be commended for their editorial policy. The book is easy to read because of the simple manner in which all the material is presented. It is a book that medical students will understand readily and practicing surgeons will find most helpful in the solution of their problems.

Essentials of General Surgery. By Wallace P. Ritchie, M.D. 8°, cloth, 813 pp., with 237 illustrations. St. Louis: The C. V. Mosby Company, 1941. \$8.50.

This book, with a foreword by Wangenstein, and with several chapters in special fields written by the author's colleagues, is apparently intended as an introductory textbook of surgery for students at the University of Minnesota Medical School. General principles are stressed, and operative procedures are wisely omitted. The objectives of the author consist "in acquainting students with the fundamental principles of surgery, in instructing them in methods which will enable students to recognize surgi-

cal disorders, and finally in teaching them what surgery can accomplish in the treatment of various diseases."

Numerous paragraph headings and subheadings, outline and tabular presentations, and elimination of much discussion of alternative methods of therapy have permitted condensation of the text to a remarkable degree. This condensation has resulted in didacticism in many cases, with omission of necessary relevant discussion and explanation. Thus, the chapter dealing with fractures refers to the Jones sling, the Bellevue splint, Buck's extension, Pott's fracture, Whitman plaster, Maxwell-Ruth traction and the Roger-Anderson method, but there is no description or explanation of what is meant by these terms.

Selected references chiefly to current literature are given at the ends of the chapters, but there is no authors' index, and the student will not find references to such fundamental contributions as Halsted's on carcinoma of the breast, although there is a brief allusion to Halsted's radical mastectomy.

In the main, the text is well written and clear, the illustrations are adequate, and the typography and the format of the book are pleasing.

NOTICES

UNITED STATES CIVIL SERVICE EXAMINATIONS

Junior Medical Officer (Rotating Internship) \$2000 a Year
Junior Medical Officer (Psychiatric Resident) \$2000 a Year

The Civil Service Commission has announced that positions are available for junior medical officer (rotating internship) and junior medical officer (psychiatric resident) in St. Elizabeth's Hospital for the treatment of mental disorders, Washington, D. C. Applications will be accepted until the needs of the service have been met, and appointments will be known as war service appointments.

The duties of the rotating internships are as follows: under immediate supervision, to admit patients, take histories, make physical examinations and record findings; to make ward rounds of inspection, note charts and record observations; to prescribe for minor ailments or acute emergency cases; to dispense medicine in emergencies; to perform minor surgical operations; to assist at major operations and in redressing; to administer anesthetics; to make routine laboratory tests and analyses; to assist at outpatient clinics in dressing and in administering vaccines; and to keep records, make up case histories and compile statistics requiring medical training. To qualify for this position, applicants must have successfully completed a four-year course in a Class A medical school before the date of appointment.

The duties of the psychiatric residents are as follows: to take histories; to make physical and mental examinations and record the findings; to make rounds of inspection; to make notes; to prescribe for and treat minor ailments; to answer correspondence relative to patients; and to assist the chief of the service in all administrative and professional duties. To qualify for the position, applicants must have successfully completed their fourth year of study in a Class A medical school subsequent to December 31, 1936, and must have the degree of either B.M. or M.D. In addition, they must have successfully completed a rotating internship of at least one year.

No written examination will be required. Qualifications will be judged on the extent of experience, education and training. Applicants must be citizens of or owe allegiance to the United States, and must be physically capable

DIAGNOSIS OF ALLERGIC STATES IN SELECTEES*

ROBERT W. HYDE, M.D.†

BOSTON

THE correct diagnosis and classification of allergic states in selectees have been difficult problems ever since the beginning of the induction-board examinations of the United States Army. Speed is a necessary component of these examinations, and the Army physicians have not always had such unlimited time, comparatively, in which to elicit and record an accurate history as their civil colleagues usually have. Furthermore, both positive and negative malingerers are occasionally seen, still further adding to the diagnostic difficulties. The examiner is therefore often faced with an unverified history of bronchial asthma and normal chest findings, but may be unable, in the limited time, to arrive at a correct, definitive diagnosis. Moreover, in a proved allergic case, it is often difficult to decide whether the condition is severe enough to warrant rejection for full military service.

In view of these diagnostic difficulties and with an eye to the future, a study of the allergic states has been made at the Boston Induction Station, with the hope that others may profit thereby.

Crandal,¹ in 1940, pointed out the gravity of the problem of allergy in the armed forces and the necessity for a complete history, and stressed the assistance expected of induction boards in eliminating the obvious cases, thereby lessening the load that would be placed on Army physicians in the subsequent treatment of men with mild cases who were accepted.

Regarding the desirability of disqualifying for general military service applicants with bronchial asthma of the mildest and most infrequent degree, evidence is available that such men are likely to be a source of future disability. In a recent paper, Andrus² points out the frequency of emphysema in men under forty in the Canadian Forces, with asthma as one of its presumptive causes. He notes

that even candidates accepted for service because of good general condition and lack of, or nonadmission of, symptoms became respiratory casualties, with an unfavorable course and ultimate discharge; such men have a tendency toward frequent illness and relapse, and form a reservoir of compensation seekers.

It is known that the patient with respiratory allergy has a higher average incidence of residual illness after being subjected to the lung irritants of chemical warfare, and medical officers have been particularly impressed with this fact. The hypersensitive respiratory tract is more easily injured than the normal by any lung irritant, and an aggravated form of a previously mild asthma often occurs, with the eventual development of chronic bronchitis, bronchiectasis and emphysema.

Army regulations specify that chronic diseases discovered in the first six months of service should be considered as having existed prior to entry into military service, thus relieving the Government of allowing compensation in such cases. Mild, infrequent asthma often does not manifest itself in the first six months of service, since the precipitating influences of seasonal pollens or infection may not be present. Hence, there is more risk of compensation than in other conditions, such as orthopedic defects, peptic ulcers and psychopathic states, that usually manifest themselves earlier. It seems clear that the allergic states deserve serious regard when an applicant for the Army is being considered.

The allergic states were not clearly understood as one disease until Cooke and Vander Veer³ showed that a large percentage of patients with asthma had histories of eczema, urticaria, angioneurotic edema and abnormal reactions to various foods. Therefore, all the older statistics, so far as the armed forces were concerned, refer only to bronchial asthma. Even with this lack, they show the importance of the problem in the past and furnish a basis for an estimate of the prevalence of

*From the Boston Recruiting and Induction Station.

†Major, Medical Corps, United States Army, Boston.

disqualifying allergic disease. In the *Medical and Surgical History of the War of the Rebellion*,⁴ it is reported that 4 men per thousand received medical attention for bronchial asthma while in service, and that 5 cases per ten thousand were of such severity that the men were discharged for this disability. Of the so-called "second million" drafted men examined at camps after May 1, 1918, 2.2 per thousand were rejected for asthma.⁵ *Medical and Casualty Statistics*,⁶ which gives the total figures for World War I, lists 1.9 per thousand as discharged from the Army for disability from asthma, and a total of 4.1 per thousand either rejected on induction or discharged for this condition. A national health survey,⁷ covering the years 1935-1936, estimated that 1.4 persons per thousand are annually disabled for a week or longer by asthma or hay fever. All these figures are in very close agreement.

It seems practical to consider the 1918 draft-examination figure as most closely corresponding

to the present situation. Since allergic dermatoses and other allergic states are not included, however, the true incidence of all allergic diseases is probably much higher.

to the present situation. Since allergic dermatoses and other allergic states are not included, however, the true incidence of all allergic diseases is probably much higher.

Three examination periods were covered in this study (Table 1). The first, from November 17, 1940, to October 20, 1941, was the entire extent of induction-board examination of selectees who had had a previous complete physical examination by their local-board physicians. The second, from October 20, 1941, to March 15, 1942, covered pre-induction examinations in which only part of the registrants had been examined previously by the local boards and in which they were returned to their homes for from thirty to fifty days before being called to camp, a tentative rejection for special diagnostic investigation being thus allowed. The third period consisted of one month under the

to the present situation. Since allergic dermatoses and other allergic states are not included, however, the true incidence of all allergic diseases is probably much higher.

EXAMINATIONS AT BOSTON INDUCTION STATION

Examinations at this station were conducted by a team of civilian specialists. The standards followed were those prescribed in MR 1-9,⁸ which specify:

Class 1-A (qualified for general military service): May include cases of hay fever, unless severe, and of acute eczema.

Class 1-B (qualified only for limited military service): May include severe cases of hay fever; mild cases of chronic asthma that have not prevented the registrants from successfully following vocations in civil life.

Class 4 (disqualified for military service): Includes cases of chronic asthma associated with chronic bronchitis and emphysema, except as stated above, and of allergic dermatosis, if severe and not easily remediable.

Because these standards allow the acceptance of mild and moderate hay fever, mild allergic derma-

so-called "single examination" induction system, in which no man had received a complete examination by the local board. During this period, the registrant was examined and, if accepted, sent to camp on the same day.

The method of arriving at the diagnosis was reviewed in the 73 cases rejected for allergic states in the first induction period to determine the number of cases presenting diagnostic difficulties, to arrive at definite diagnostic criteria, and to establish what special investigations and findings were of most value.

Owing to the intermittent manifestations of most allergic conditions, occurring perhaps for only short intervals or at seasons other than that during which the selectee was being examined, it was impossible to use the same criteria of diagnosis that one would employ in clinical practice, in which the patient usually comes for medical examination at the time symptoms are apparent: in practice, full reliance can be placed on the history, whereas in examination by induction boards, an unsubstantiated history alone is not adequate

cause for rejection, because of the possibility of various degrees of malingering or concealment of disability.

In the 73 men rejected for allergic states, the following findings were of diagnostic value:

There were 6 cases of eczema and allergic dermatosis. The abnormal skin condition was visible at the time of examination, and a history of its relation to specific provocative irritants was obtained. (No registrant gave a history of an allergic dermatosis that was not apparent at the time of examination.)

In the 4 severe cases of hay fever, there was visible evidence of nasal allergy at time of examination, and the severity was verified by history as disabling.

There were characteristic asthmatic chest signs on routine examination in 32 of the 63 cases of bronchial asthma.

The fact that 51 per cent of the selectees with bronchial asthma had definite sibilant rales on auscultation, and that in an additional 6 per cent such signs were found later during the same day, emphasizes the value of this type of examination. Although the paroxysms of bronchial asthma are,

TABLE 2. Comparison of the Incidences of Other Abnormalities in the Allergic and Control Groups.

ABNORMALITY	ALLERGIC GROUP	CONTROL GROUP
	%	%
Chronic sinusitis	10	0
Nasal polyps	6	0
Deviated septum, deformed nose, basal septal ridge, dislocated nasal cartilage, basal spur or defective hearing	15	18
Dorsal kyphosis, severe	4	1
Neuropsychiatric conditions	20	20
Sympathetic instability	4	1
Chest expansion (average)	6 cm	6 cm.

in most cases, of short duration, one forgets that it often takes weeks for the chest signs to disappear entirely and that, in many severe cases, the chest signs are seldom absent, owing to the presence of superimposed emphysema and chronic bronchitis or bronchiectasis.

In the remaining 31 cases of bronchial asthma, which at the time of examination showed no rales and in which the diagnosis was made by the internist on an apparently unequivocal history, the special examination or findings that were of assistance in substantiating this diagnosis were: re-examination of chest eliciting characteristic musical and sibilant rales, 6 cases; documented history, 2 cases; nasal allergy, 3 cases; allergic dermatosis, 3 cases; and eosinophil count over 5 per cent, 2 cases. Although the finding of nasal allergy, or allergic dermatosis in a case of bronchial asthma is not positive verification of a suspicious history of asthma, it is evidence of an allergic state and hence may be considered at least partial sub-

stantiation. The same thing may be said, with certain reservations, of an elevated eosinophil count.

To determine the significance of other abnormalities found in the allergic group, the records were compared with a control group, made up of the 2 cases rejected following each case rejected for an allergic state (Table 2). Although the series is small (73 allergic conditions, 144 controls), certain tentative conclusions may be drawn.

Abnormalities of nose. The finding of sinusitis and nasal polyps should be considered tentatively at least as substantiating a history of an allergic condition. Although it is known that the occurrence of nasal sinusitis in bronchial asthma may be purely coincidental, the relation is so common that the error can be considered insignificant. Francis, quoted by Lord,⁹ found nasal abnormalities in 14 per cent of his 442 cases of asthma, and Rackemann¹⁰ states: "The clinical picture of asthma is not limited to the pulmonary symptoms. Lesions of the paranasal sinuses are part of it." That patients with sinusitis only rarely have asthma is, of course, well recognized. Other abnormalities of the nose and throat do not appear to be of significance in the diagnosis of allergic states.

Orthopedic abnormalities. Although more cases with marked dorsal kyphosis were recorded in the allergic group than in the control group, the number was far less than was expected. It is a fact that severe bronchial asthma in childhood produces more or less deformity of the thoracic structure. However, such defects were not sufficiently striking to be recorded by either orthopedist or internist in the rapid routine examination. Hence, a special examination of the thoracic structure may well be indicated in all cases giving a history of asthma, for although it might be expected that the chest expansion would be altered, this was not shown on routine examination.

Neuropsychiatric abnormalities. Although no quantitative and little qualitative difference could be found in the neuropsychiatric abnormalities in the two groups, the diagnosis of the allergic state was included as part of the neuropsychiatric diagnosis in 12 per cent of the 73 cases. Since the neuropsychiatric examinations were performed by a number of different examiners with very limited time at their disposal, the diagnostic criteria were not uniform. The method by which the neuropsychiatric diagnosis was made therefore requires clarification. Undoubtedly, what the psychiatrists had in mind was the psychosomatic component of allergic states. This psychiatric aspect has been referred to by others.¹⁰

X-ray findings. The chest roentgenogram was recorded as normal in all but one case of the allergic series, showing definitely that a negative finding does not rule out bronchial asthma. It was believed, however, that a greater number of positive findings of emphysema, pulmonary fibrosis, low fixed diaphragm and bronchiectasis should have been made in cases of long-standing, severe, bronchial asthma, that the routine examination was not giving sufficient information and that additional roentgenographic study was advisable. The 4-by-5-inch stereoscopic photo-roentgenogram without grid in routine use gives an exaggeration of the lung markings at the bases that has to be minimized in interpretation. It may prove advisable to take 14-by-17-inch films in men with a history of long duration and severity.

Verification and detailed history. It is hard to conceive of a registrant with bronchial asthma of sufficient severity to warrant rejection who has not sought medical attention at some time; therefore, when such verification is easily available, it is often the most efficient method of substantiating the diagnosis. The statement from a reputable physician or clinic of having observed the patient in attacks of asthma was considered adequate to substantiate the history.

Obtaining a detailed allergic history, including the descriptions of attacks and all manifestations of allergy, is far different from merely hearing the registrant's statement that he has bronchial asthma. It is difficult to give such a history without an intimate subjective knowledge of the disease. For this reason, when other evidence was not easily available, the detailed history was relied on in a few cases; however, later study proved that the greatest advantage of the complete history was to determine the exact nature of the case so that a search could be made for whatever manifestations might be expected.

Eosinophil count. Although the eosinophil count is elevated in some parasitic conditions, in this locality they are sufficiently rare so that a count of 4 per cent or over is regarded as substantiating the allergic state, provided that no history of these parasitic and certain other conditions is obtained.¹¹ It has been shown by Baagöe¹² that the count may remain elevated one month after an attack—a fact that makes it exceedingly useful in diagnosis, especially in registrants with a history of an asthmatic attack within a few weeks but with no objective evidence of the disease.

Eosinophil counts were made in a small series of suspected cases and nonselected controls. In the control series (24 cases), no eosinophil count was over 3 per cent. The counts in 6 cases suspected of allergy and proved negative were less than 2 per cent. When eosinophil counts were made in the remaining 18 patients, disqualified because of allergic states, the counts were over 5 per cent in 5 (28 per cent).

First Series

Four selectees out of the 18,707 examined in the first period at the Boston Induction Station were discharged from camp on Certificate of Disability Discharge for bronchial asthma. This is not the total figure, since it does not include those examined in this and discharged in other corps areas, but it probably comprises roughly 50 per cent of the total. The records of these cases were reviewed. In none was there any history of allergy or respiratory abnormality. In only one were there findings that might have aided in a diagnosis of allergy. In that case, there was dorsal kyphosis, poor posture and a chest expansion of only 4 cm. This suggests that more specific questions should be asked to elicit a history of allergy and that more attention should be given to abnormal thoracic structures.

Diagnostic errors were apparently less frequent than might be expected in such rapid routine examinations. A few selectees who were rejected for bronchial asthma on the finding of sibilant and musical rales and a doubtful history later returned and were accepted. With the great num-

ber of acute respiratory conditions seen at some periods, such an error seems unavoidable but would be minimized by adherence to the present criteria and by following Paragraph 49b of MR 1-9, which states that Class 1-A may include cases of "acute bronchitis, providing acceptance is temporarily deferred until a final examination shows recovery without disqualifying sequelae." When this procedure is followed, roughly half return completely recovered; the rest continue to have chest signs over a period of months and are rejected for chronic bronchitis or bronchial asthma.

Rejection was considered in a few cases in which a verified history of childhood asthma was obtained, but with no symptoms in the previous five years. Such a history is inadequate proof of bronchial asthma, and is of such doubtful significance in adult life that disqualification appears unwarranted. In 2 cases in which a clinical diagnosis of bronchial asthma was made, the x-ray findings were those of moderately advanced pulmonary tuberculosis. Several selectees, believing that they had asthma, based on an isolated attack of "wheezing" several years previously for which they had sought medical attention, had been skin tested and instructed to avoid certain allergens. Such isolated attacks do not warrant a diagnosis of bronchial asthma.

No frank case of malingering of feigned allergy was discovered in the examinations of the first period, although several were suspected in which the allergy was proved; several cases were found, however, in the last examination period. Negative malingering was commoner. Three selectees, ignorant of the seriousness of the offense, concealed from the examiner the fact that they had had severe bronchial asthma when asked general questions concerning their past illnesses. Three selectees answered in the affirmative to all questions regarding allergic symptoms and were found to be nonallergic; all, however, were mentally deficient.

Second Series

Little information was gained in the second pre-induction examination period, although 86 men were rejected for allergic conditions. This lack of information was largely due to the fact that doubtful cases could be classed as "tentative rejections" and requests made for such examinations and verification of history as were necessary for diagnosis. This removed the pressure of having to make a definite decision on the day of examination, and thereby eliminated the stimulus to investigate diagnostic criteria. Theoretically, this method should be extremely accurate because more study can be made of the cases. The results were illuminating, because none of the cases were

returned with any information that could not have been obtained on the day of examination.

In this period, a detailed study was made of the first 4000 selectees. Of this number, 18 were disqualified for allergic states; all were verified by history. Musical and sibilant rales were heard in 11 cases; 1 man had dorsal kyphosis and 3 had chronic sinusitis and nasal polypi. Neuropsychiatric substantiation was obtained in 1 case, and increased bronchial markings on x-ray study in 1 case. Seven tentative rejections (28 per cent) were made, with requests for verification of history, eosinophil counts and skin testing.

Third Period

With the knowledge gained in the first two periods, a study was made to determine the efficiency of the examinations in the first 68 cases in this period in which the registrant gave a history of bronchial asthma (Table 3). Of these, 58 were

TABLE 3. *Pertinent Findings in 58 Selectees Disqualified for Bronchial Asthma.*

FINDING	NO. OF CASES	PER CENT
Documentary history	28	48
Eczema	1	10
Sinusitis or verified history of sinusitis	—	12
Sibilant or musical rales on auscultation (either on examination or re-examination)	45	78
Thoracic structural abnormalities (dorsal kyphosis or increased anteroposterior dimensions on examination or re-examination)	20	35
X-ray abnormalities	1	10
Emphysema	2	
Pulmonary fibrosis	1	
Fixed low diaphragm	1	
Bronchiectasis	1	
Neuropsychiatric conditions (psycho-neurosis with allergy or psychosomatic syndrome)	6	10

verified and the registrants rejected. Eight men were accepted, 3 because the condition had not been present for five years, and 5 because of the absence of any evidence of asthma at the time attacks were claimed or because of documentary evidence that the asthma did not exist. Two cases were proved to be recurrent acute anxiety states, and the men were consequently rejected.

In all cases, a detailed history elicited an intimate subjective knowledge of the disease, and one or several of these pertinent findings were present. The findings in this series confirmed the conclusions arrived at previously and also showed that more special attention to chest roentgenograms and the thoracic structure demonstrated more significant abnormalities than had been seen on previous routine examinations. It could not be decided whether the discovery of malingering in 6 cases, in the last induction period, demon-

strated error in the previous examinations or a general increase in attempted evasion of military service.

DISCUSSION

The diagnosis of allergic states by examining boards resolves itself into a detailed study of each case, presupposing an intimate knowledge on the part of the examiner of the many manifestations of these conditions, and the residua apparent during the intermissions between acute episodes.

Every registrant is asked whether he has ever had asthma, bronchitis or hay fever. His history form is inspected to see if he has mentioned these or other related conditions. If a history of bronchial asthma is elicited, especially careful attention is given to auscultation of the chest. If there has been an attack within three weeks, fleeting musical rales may frequently be expected. Many men with the history of an old severe asthma, but with no attacks within a few years, are found to have chronic asthmatic bronchitis and emphysema at all times.

The complete allergic history is carefully taken, with special attention to determine from the duration, frequency, severity and precipitating factors just what condition would be expected at the time of examination. In all cases of asthma, and especially if the story is one of a severe asthma in childhood, the chest contour must be carefully inspected for increased dorsal kyphosis, barrel chest and increased anteroposterior diameter. A note should be sent to the radiologist to give the chest film special attention and to take a 14-by-17-inch film, if necessary. In men with a history of attacks within two months, an eosinophil count should be requested if the diagnosis is not otherwise verified. The history should include a detailed account of all previous medical attention. This often points out the severity and disabling nature of the condition and also gives the sources from which a documented history may be obtained.

In all cases, the skin must be carefully inspected, especially the face, ears and elbows, for eczema, which is often present between asthmatic attacks. The skin should be stroked to test for dermatographia. The results of the nose and throat examination should be noted, and the finding of nasal allergy, sinusitis or nasal polypi should be considered significant. All questions of purulent nasal discharge and chronic rhinitis should be solved by x-ray examination of the nasal sinuses. The results of the neuropsychiatric examination are studied, and the inclusion of the diagnosis of allergy as part of the neuropsychiatric diagnosis is considered substantial verification.

CONCLUSIONS

At the Boston Recruiting and Induction Station, 220 registrants out of 45,000 examined, or 0.5 per cent, were disqualified for general military service because of severe allergic states. This number compares closely with the known prevalence of these conditions in the general population of this age group.

The errors of the examination were considered. A known 4, and an estimated 8, selectees from the first 18,707 examined were discharged from camp for bronchial asthma within six months. In none of the 4 cases was a history of the condition obtained.

It is believed that even men with mild cases of asthma should be disqualified for general military service because of the probability of frequent illness, serious residua after subjection to chemical warfare, and greater risk of compensation.

Contrary to what might be expected, no information was gained in the preinduction period by the making of tentative rejections for further information and examination that could not have been gained on the day of examination.

It was found that an adequate diagnosis could be made from routine examination in only 60 per cent of the cases. This indicated the need for investigating what findings and examinations were of most value in substantiating the diagnosis; these include the presence of nasal sinusitis or nasal polypi, examination of the thoracic structure for dorsal kyphosis and an increased anteroposterior

diameter, positive neuropsychiatric findings, positive chest findings on auscultation, a documented or verified allergic history and a high eosinophil count. The roentgenogram was of assistance in only from 2 to 10 per cent of cases, depending on whether it was a routine or special examination; hence, a normal chest film in no way eliminated bronchial asthma.

With the assistance of these findings, and by setting not too stringent criteria for diagnosis, an examining board will find little trouble in the diagnosis of allergic states.

ASCORBIC ACID DEFICIENCY ASSOCIATED WITH GASTRIC LESIONS*

CHARLES C LUND, MD.†

BOSTON

IN recent publications, Lund, Crandon and Dill³ have presented data concerning the relation of ascorbic acid to the healing of wounds. These data were secured by a study of patients whose wounds failed to heal. From these studies, conservative conclusions were drawn concerning the relative importance of ascorbic acid and various other factors (technical and chemical) as causes of failure of healing. The authors believed that, in the series studied, ascorbic acid deficiency caused fewer failures of healing than technical factors did. As a result of a similar study of cases with disrupted wounds, Hartzell, Winfield and Irwin⁴ have taken the same conservative position, placing ascorbic acid deficiency among other factors as a possible cause of delayed or poor healing. Holman,⁵ who studied routine surgical admissions, found that many patients had low blood plasma levels of ascorbic acid, but he did not state that disruption occurred in any of the particular cases studied. Bartlett, Jones and Ryan⁶ showed that, in addition to low plasma ascorbic acid levels, many patients had abnormally low clearance curves in the plasma and low excretion in the urine after the administration of test doses. A recent paper by the same authors⁷ presents experiments in which the tensile strength of healing tissues of animals and men were tested and the ascorbic acid content of the healing tissues determined. These studies show that low plasma levels are associated with low levels in the healing tissues, and that this, in turn, is associated with delayed healing. Wolfer and Hoebel⁸ studied several cases of gastrointestinal carcinoma and other conditions. One patient without treatment was found to have a very low level of plasma ascorbic acid after evisceration. Other patients with low levels were treated, and no evisceration occurred. Ludden, Flexner and Wright⁹ found, in 23 cases with gastric lesions, that only 1 patient had a normal ascorbic acid reserve, and 1 had frank scurvy. They report that 7 gm of ascorbic acid was necessary to saturate the latter patient. Hunt¹⁰ studied the problem of vitamin C and healing in

both experimental animals and man. A particularly interesting part of the study was that done on 28 patients who came to autopsy shortly after surgical operation. He found that in 8 there was microscopic evidence of failure of deposition of collagen in the wounds; 5 had disruption of the abdominal wounds, and 3 had leakage of anastomotic suture lines.

The present communication is concerned with data on a group of patients with gastric lesions. These cases are of especial interest because ascorbic acid deficiency is very common among them, not because of any direct metabolic effect of the disease, but purely because of deficient dietary intake of the vitamin. In this study, an attempt was made to estimate as closely as possible the tissue reserves of the vitamin. These reserves are what is probably important in the healing of the wound rather than the output in the urine or the amount in the blood-plasma, both of which may be affected by changes much more rapidly than the reserves are. It was hoped that by focusing attention on the reserves a better understanding of the problem might be secured.

METHODS

Dietary history. Analysis of the patient's diet, one of the many ways of studying the ascorbic acid status, is available to any physician and needs no laboratory tests. Without such tests, however, it can give only part of the picture, but the part given is so important that even when laboratory tests are available it must not be omitted. For some time, there have been available complete tables giving fairly accurate analyses of the vitamin C content of all usual American foodstuffs.¹¹ By taking a dietary history and calculating from the tables, one may make a fair estimate of the vitamin C intake over as long a period as the history is reliable. It must be realized that studies for a day or two are of little value. What is needed are averages over long periods. Ralli et al.¹² have shown that, when diets are changed, the blood plasma level changes with them, and rather promptly becomes adjusted to the new level of intake, except that no increase in intake can cause a further rise in the level after the tissues and blood become saturated. From the length of time shown by Crandon, Lund and Dill³ to be necessary for the de-

This work was aided by grants from anonymous donors from the Wellfleet Fund and from Hoffmann-La Roche Incorporated, Nutley, New Jersey. Assistance in securing the data was in part furnished by the personnel of the Work Projects Administration (Projects 1466*, 17530 and 21307).

†Assistant professor of surgery, Harvard Medical School; visiting surgeon in 1941-42 to Boston.

velopment of scurvy in a healthy man, it is certain that the adjustment of the reserves to changes in the diet is much slower than the adjustment of the blood plasma level. In giving consideration to the dietary calculations, one must take account of the possible interference with intake caused by vomiting and the interference with absorption caused by diarrhea. There is also evidence that the needs of the system are increased in conditions causing increased metabolism, such as fever and hyperthyroidism. In this study, the dietary calculations were based on the average intake for one month prior to the first blood test. It is realized that a longer period of consideration would be helpful if there were marked variations in intake prior to a month, but it was found to be impractical to evaluate data that went back farther than this.

Blood plasma studies. If the patient is on a definite daily intake of vitamin C and is in a constant state so far as absorption and metabolism are concerned, a single plasma determination will give a fair index of the degree of saturation. Unfortunately, however, a very short period of reduced intake or increased utilization will affect the plasma level much more than it will affect the tissue reserves. A single determination showing a saturation level (about 1.0 mg. per 100 cc.) is all that is needed to prove that a patient's reserves are saturated, but a determination of 0.00 may be found in a person who has a 75 per cent reserve, and the same value may be found in a patient with scurvy.² A low value with high reserve may be due to illness, operation,¹³ starvation or vitamin C deprivation of only two or three weeks' duration.

When a low value has been found, one can, however, determine how low the depletion in reserves is by replacing the vitamins and measuring the amount and time needed to achieve saturation. Two general types of saturation tests have been used in the past. In one, hourly determinations of the plasma level are made after a test dose of, usually, 1 gm.¹⁴ The shape of the resulting curve indicates the degree of depletion. The other, and the one used in this study, is to give daily doses, usually 1 gm. each, and determine the level on the following mornings.¹⁵ A true case of scurvy will need four to six doses before the patient shows a normal level in the morning.² If one finds, however, a saturation level on the second morning, one can be sure that the patient had half or more of his normal tissue reserves before the test began.

Vitamin C in white blood cells. Butler and Cushman¹⁶ showed that the normal person with saturated vitamin C reserves has a level of 30 to 40 mg. per 100 gm. in the white blood cells. They,

and Crandon, Lund and Dill,² have shown that this level drops off much more slowly on deprivation than the level in the plasma does. However, even this value does not always have a direct relation to the reserves, since the level reaches zero some time before the symptoms of scurvy appear. Values for the white cells were included in the data on a few of the cases in this paper.

Estimation of reserves. The estimate of ascorbic acid reserves is made on the basis of all the data available in each case. In all cases except Case 1, there was evidence of at least two of the following kinds: history, simple plasma determination, simple white-cell determination, and determination of plasma or white cells after test doses. When diet or simple plasma or white-cell determinations were the only data available, the reserve was taken at the level suggested by the one that indicated the position nearest to its normal. If determinations were made following test doses or treatments, the results of these tests were made the basis of the estimate, as follows: if the plasma value was found to be 1.0 mg. per 100 cc. the morning after a dose of 1.0 gm. of ascorbic acid, the value was entered as 75 per cent because, no matter what the original plasma determination showed, the reserve could not have been appreciably lower than this; on the other hand, if the plasma determination was still 0.0 mg. after three daily doses of 1.0 gm., the reserve was entered as 0. Other results were entered at intermediate levels depending on the best estimate of the reserve.

DATA

Table 1 presents data on 18 patients with non-radical, elective operations for ulcers of the stomach and duodenum. The indications for operation were intractability to medical treatment, obstruction or bleeding or some combination of these. The first column in the table shows the usual dietary intake during the month prior to study. It should be noted that most of the cases had very low intakes. The second and third columns show the pretreatment plasma and white-cell values. The fourth shows the estimate of the reserves. In some cases, particularly Cases 3 and 9, higher values are given than can be directly estimated either from the diet or the plasma value. The estimate in such cases was made on the basis of a later saturation test that proved that neither the history nor the plasma value indicated the true situation. In general, whatever evidence indicated the higher value for the reserve was considered to be most nearly correct for a particular case. The fifth column indicates the amount of ascorbic acid given either by mouth or intrave-

nously prior to operation or up to four days after operation. The sixth shows the reserve established by the addition of this treatment to the prior reserve. The seventh column gives the type of oper-

long time and was in a particularly depleted condition in every way. He had so little vitamin C reserve that he was very close to scurvy. Although this deficiency was taken care of, it is possible that

barely possible that the very low level of vitamin C may have contributed to his death. The patient in Case 12, which has been previously reported,¹ had a disruption due largely to scurvy. Case 17 was that of a man who had been vomiting for a

In a large number, including all but one that had complications, they were studied after complications arose. For this reason, the series is not a fair sample of the work in the hospital, and the high mortality of these cases is much higher than

the hospital average. The very low values for plasma ascorbic acid must be viewed in the light of the time the blood was taken. Both the operations¹³ and the complications probably depressed these levels.

Table 3 shows data similarly arranged for 15 cases having major operations for the removal of benign gastric and duodenal lesions. It will be seen that more of these cases had fairly good vitamin C reserves prior to the immediate preoperative period and that many of the deficient cases were

tured gastric ulcer are not included because post-operative depressions of the value make direct comparison with the other cases impossible). Levels of less than 0.10 mg. were found ten times in the same number of operations. White-cell values were available in only a few of the cases. None showed a saturated level (30 mg. per 100 gm.), and 7 out of 13 patients gave evidence of a very depleted, but not necessarily scorbutic, state.

It is also clear that very few of the cases showed evidence of saturation before treatment. In fact,

treated with ascorbic acid either just before or just after the operation. It should be noticed that 3 patients were studied only after complications had set in, ten, eight and ten days, respectively, after operation.

DISCUSSION

Status of Ascorbic Acid Reserves Before Treatment

A total of forty-eight gastric operations were done on 43 patients. If one takes a conservative position in regard to diet by considering that a daily intake of 50 mg. should maintain a sufficient reserve for all purposes, the histories indicated that in only 7 of 43 patients was this level recorded. In 16 of 43 cases, the record showed a daily intake of less than 10 mg. However, in 5 of these, the history must have erred because other data showed higher reserves than such an intake would be likely to maintain. If one considers that a plasma level of 0.60 mg. per 100 cc. shows a reasonably saturated condition, it is evident that this level was found in only 4 of 31 cases (the cases with a rup-

tured gastric ulcer are not included because post-operative depressions of the value make direct comparison with the other cases impossible). Eight cases were rated at 10 per cent or less.

Status of Reserves at Time of Healing

Early in the study, it was found that many cases with very low plasma levels healed properly in every way, so that no effort was made to have the condition corrected in all cases at once. Therefore, many cases that probably should have been treated with ascorbic acid were not. It will be seen from the "preliminary treatment" and the "reserves at time of study" columns that some cases were not treated, but that many were. The latter is particularly true in the cases with radical operations. It is also seen that, in many cases, treatment was started or continued after the primary healing period was over. This was especially so in the cases of ruptured ulcer with complications.

Importance of Reserves at Time of Healing

It is impossible to visualize systematic differences of results in accordance with differences in the

ascorbic acid reserves by inspection of the three tables already presented. However, Table 4 summarizes some of these data in a form in which they can be visualized. Everything is left out except the vitamin reserves during the healing period and the results. The cases are divided into three groups: those with reserves of 0 to 20 per cent, 25 to 50 per

It is well realized that it is dangerous to claim that diverse postoperative complications are in any way due to vitamin C deficiency. Lund and Crandon³ have already presented data showing lack of correlation between vitamin C levels and the development of postoperative pneumonia. Others, however, especially Hunt,¹⁰ have believed that

TABLE 4 Complications and Deaths following Operations for Gastric or Duodenal Ulcer in Relation to Ascorbic Acid Reserves at the Time of Healing

	50 per cent or over	1	11	3	3	35	18
	Total or average	48	28	10	10	42	21

cent and 55 per cent and over. Results are also divided into three groups: recovery without complications, recovery after complications and death. The complications are all grouped together.

The most significant data in this table are found by comparison of the results (percentage of complications and deaths) derived from Tables 1 and 2 with the corresponding figures from Table 3. The number of cases is small, and conclusions derived from such a small series of cases must be guarded. There is, however, an apparent correlation between complications and deaths and low vitamin C reserves in the cases presented in Tables 1 and 2, but none in Table 3. What does this mean? Only a suggestion can be made. Such operations as closure of a ruptured ulcer and gastroenterostomy are so simple that technical errors are very unlikely. Therefore, if there are marked variations in the medical aspects of the cases, these variations rather than technical ones are likeliest to determine complications. On the other hand, the technical difficulties encountered in the major gastric resections were so frequent and so great that the variations, if any, resulting from the medical aspects of the cases did not show up.

many cases of postoperative peritonitis are due to failure of wound healing. It will be seen that all the complications of the cases listed in Tables 1 and 2 comprised complete disruption of the wound or peritonitis, which, in every case, could have resulted from failure of the gastrointestinal suture line to heal, except the complication in Case 1, Table 1. The data suggest that low vitamin C was a major complication of the remainder of the cases.

Vitamin Treatment of Surgical Cases

The vitamin treatment, if any, given these patients was usually limited to ascorbic acid, but in a few cases, one or more of the following vitamins were given: vitamin A, vitamin D, thiamine and niacin (nicotinic acid). All the cases of gastric resection had transfusions of at least 500 cc of whole blood, and a few of the others received similar treatment.

The fact that, in many of these cases, no benefit can be shown to have resulted from vitamin treatment does not indicate that it was useless. The failure to demonstrate results may mean only that the treatment was "too little and too late."

must not forget that most of the cases showing more than 50 per cent depletion below saturation of ascorbic acid may have had more serious, but unrecognized, deficiencies of other vitamins, minerals or even of types of protein. It is more than possible that some of these other deficiencies are more significant than that of ascorbic acid. As methods of study become available, they should be applied to such cases. In the meantime, the position taken by Holman⁵ of giving large doses of all vitamins to all cases undergoing major surgery may be a wise one. It should also be remembered that, when vitamins are ordered, they should be given parenterally if there is any chance of poor absorption.

CONCLUSIONS

Very few of 45 patients who underwent operations for gastric lesions had a normal ascorbic acid intake, plasma level, white-cell level or reserve.

A few cases had such low reserves that they must have been very close to scurvy.

The greatest number of cases had from 20 to 50 per cent of normal reserves.

When nonradical operations were performed, more complications and deaths occurred in the patients with low reserves than in those with high reserves.

No more complications or deaths occurred in patients with low ascorbic acid reserves after radical gastric operations.

It is suggested that more and better vitamin treatment is indicated in cases coming to gastric surgery.

PRACTICAL PSYCHIATRY WITH ADOLESCENTS

III. Technic of Psychotherapy for the General Practitioner

DANIEL J. SULLIVAN, M.D.,* AND OTTO BILLIG, M.D.†

ASHEVILLE, NORTH CAROLINA

IN the first paper¹ of this series, a general discussion of the problems of the adolescent outlined various difficulties of adjustment met by the adolescent as he advances from late childhood to early adulthood, and the opportunity for help from the family physician was stressed. In the second paper,² a practical method for psychiatric examination was detailed, the minimal but necessary technical knowledge being explained. In this concluding paper, methods of psychotherapy and illustrative case histories are presented, so that the essentials for a mental-hygiene approach to these patients can be readily utilized.

The older child and the adolescent do not need excessive care in handling the many problems of adolescence; they can do most of the adjusting themselves. What they do need for the most part is understanding rather than actual help and, particularly, encouragement to seek and maintain an increasing independence of family. How unsuccessful an adolescent is in meeting his problems is expressed by his conduct, which is an exaggeration of behavior patterns formed in early childhood.

Personality reactions underlying adolescent behavior result in three general types: the paranoid, who believes that others always "pick" on him, resents correction, and is constantly dissatisfied; the introvert (schizoid), a shy, seclusive person who retires into daydreaming and fantasy formation; and the offensive patient, who is defiant, antisocial and the leader of rebellious groups, and who basically has a great deal in common with the paranoid. These types occur mildly at some time or other in all adolescents, but are pathologic when any one becomes marked and fixed in a certain person.

The commonest feeling resulting from unsuccessful adjustment is inferiority. Ordinarily, such feelings result from one or more of the following: an oversolicitous mother who prevents the child from "growing up" and hence makes him unable to hold his own in competition; a stern father who sets standards too high for the child to reach with any personal satisfaction of measuring up;

physical defects magnified by overzealous parents and others; and relative mental dullness in a child who is made to compete with children of higher intelligence. Feelings of inferiority usually develop with adequate bases, whereas a so-called "inferiority complex" is an exaggerated degree of such feeling.

As described in the second paper of this series, the important investigative and diagnostic points may be enumerated as follows: neurotic traits; daydreaming and fantasy life; personal ambition; loves and attachments; secret fears and uncertainties; psychic trauma; sexual knowledge or misbeliefs, experiences and fears; intrafamily relations; and any symptoms of a psychosis. After determining the presence, quality and quantity of these traits, along with any other evidences of maladjustment, one is in a position to outline a plan of treatment.

METHODS OF TREATMENT

Explanation, reassurance and desensitization are the essential methods of direct psychotherapy so far as the general practitioner's training and time permit. This, of course, presupposes that he has gained the confidence of the adolescent and can act as a sort of father-confessor to him. The combination of the traditional "family physician" and modernization by training in psychology and psychotherapy is the ideal sought. One cannot tell these adolescents to "buck up," "forget it" or "cut out the kid stuff"; one cannot threaten them with reform school or insanity, or laugh at their often ridiculous beliefs concerning sex, methods of physical culture to become a strong man, fantasies of achieving renown and so forth. Instead, one must permit them to unburden completely, encouraged by gentle questioning and fortified by the absence of any disciplinary or condemnatory atmosphere. Later, the encouraging of self-discipline and of the recognition and acceptance of personal responsibility can be gradually inculcated.

When the whole story, or most of it, has been obtained from the patient, and the available outside history has been evaluated, the process of desensitization should be the next step. All experiences and ideas that have caused the adolescent acute shame, embarrassment, anxiety or fear should be calmly and completely explained; the patient

*Assistant director, Highland Hospital, and medical director, Asheville Community Mental Hygiene Clinic, Asheville, North Carolina; instructor in psychiatry, Duke University, Durham, North Carolina.

†Associate in psychiatry, Highland Hospital, Asheville, North Carolina; instructor in psychiatry, Duke University, Durham, North Carolina.

should be particularly impressed with the fact that he is suffering the emotional "growing pains" subsequent to trying to discover himself as he rapidly matures. Pointing out evidences of the physical changes of puberty as coincidental physical "growing pains," the analogy being based on the fundamental unity of mind and body, is a good way to combine answers to both emotional and physical problems.

Explanation, reassurance and desensitization are direct methods of psychotherapy, but the indirect methods, such as a daily schedule of activities to fill up the adolescent's day, a modification of parental attitudes, and major or minor changes in school environment, are often as helpful.

The *daily schedule* should include school hours followed by an interval spent in a part-time job, athletics or group hobbies; evenings should be reserved for study and individual hobbies. Friday and Saturday evenings should be set aside for motion pictures, dances and parties, Saturdays for part-time jobs and athletics or other outdoor activities (boy scouts, hikes, nature clubs and so forth) and Sundays for church attendance and outdoor activities or quiet social groups at home. Idleness and loafing rather quickly foster restlessness and dissatisfaction, loss of interest and initiative toward the future, and even frank delinquency.

Hobbies should be of indoor and outdoor, and of individual and group types. Indoor hobbies have the advantage of year-round availability, whereas outdoor hobbies are usually seasonal or at least partially dependent on the weather. Solitary hobbies are useful for the adolescent who is particularly restless and flighty, since they promote perseverance and concentration. Group hobbies afford social contacts that are primarily of common intellectual interest, but adequate overflow into less impersonal relations readily occurs. This type of hobby is well worth fostering in the shy adolescent who feels woefully inadequate but often can be drawn out; in others, the intellectual liaison is established, and then, gradually, the aura of friendship appears.

The adolescent should be encouraged into actively investigating the subject of hobbies; he should be given some good references³⁻⁵ and should be encouraged to patronize the local library, Y. M. C. A., Boy Scouts and organized hobby groups. The following are more specific suggestions of hobbies:

Indoor:

Collecting — stamps, coins, autographs, minerals, semiprecious stones, Indian relics, curios of all types, antiques, art works and books.

Plants and animals (raising and training, or just pets).
Manual arts — woodworking, metal working, model making, leather working and weaving.

Fine arts — drawing, painting, engraving, sculpturing, music, literature and photography.

Entertainment — magic and sleight-of-hand, impersonations and fortune telling.

Sciences — astronomy, radio, chemistry and microscopy.

Outdoor:

Walking, hiking, camping, fishing, hunting, boating, exploring, sports, mineralogy and nature study.

Group:

Dramatics, hobby clubs, study groups, and actual work in organized charities.

Group activities should occupy a large part of the adolescent's time, since it is vital for him to learn how to get along with others. Although a continual round of group activities may keep him from learning the value of quiet concentration and serious thinking, in the absence of many group contacts there is the very serious danger that the patient may develop a shy, withdrawn, introverted personality that is conducive toward dementia praecox (schizophrenia). Extracurricular activities at school, — clubs, orchestra and debating and dramatic societies, — church social groups, special organizations such as the Y. M. C. A., Y. W. C. A., Boy and Girl Scouts and their junior divisions, and the National Guard or similar military organizations all utilize the physical and mental energy of the adolescent, besides socializing and maturing him.

Sports are almost a fetish in this country, at least from the competitive standpoint. The tendency is for the quickest and strongest, because they make up the "school team," to have all the advantages of organized sports. Recently, the insistence on intramural sports in which all the students get a chance to play the commoner sports with those of their own general skill has done much to democratize sports. As much accent should be placed on "durable" sports, such as tennis, golf and hiking, which the player can continue when he gets older, as on intensely group-competitive sports, such as football, baseball and basketball. Also, the competition should not outweigh the sheer fun and relaxation inherent in sports.

Keeping a *diary* is useful in selected cases to get a better understanding of the adolescent, who can often write about his troubles better than he can talk of them. One should rarely use this method in the very introspective adolescent, since it will make him more so and such patients are difficult in the first place. A compromise method is note-

taking, in which the adolescent jots down at odd moments the things that he considers most difficult for him to understand or seem to produce unusual emotional reactions.

*Modifying the family situation*⁶ is necessary in practically every case, this procedure being omitted when the adolescent comes spontaneously and sometimes secretly so far as the family are concerned. Since the parents are usually the source of financial support, one must postpone fee expectation until the adolescent permits his parents to know that he is seeing a physician, or let the bill go indefinitely until he himself can pay. If the adolescent allows his parents to know, and in serious cases one may occasionally seek a secret conference with a parent, it is usually necessary to advise a modification of the parents' attitude toward the child. The parental attitude may have been condemnatory, prying, sarcastic, nagging or cold. The fault is seldom all on the adolescent's side, often, all he needs is a little wise neglect and absence of parental overattention.

A disconcerting fact, but one that does not negate the recommendations given above, is the observation that the parents are essential in preventing the development of criminally delinquent adolescents. The Gluecks⁷⁻⁹ found that in 60 per cent of 500 young criminals and in 58 per cent of 500 delinquent women there was a background of broken homes. If a parent is abusive or domineering or alcoholic, the adolescent will have trouble adjusting himself, both because he is antagonistic to the immediate situation and because his personality has been scarred through childhood by the baneful influence of such a parent. If the family situation is unusually bad, it may be advisable to recommend a foster home or care by congenial relatives.¹⁰ In planning the removal of the adolescent from the home, Rogers¹¹ points out that success will occur if the patient finds emotional security, a sense of acceptance and a relief from fierce sibling rivalry, and if his emotional ties to the parents are not strong. Rogers concisely charts the criteria for consideration in foster placement, although chiefly used in children, they are in a large measure applicable to adolescents.

The classic adolescent behavior of horseplay, loudness of speech, atrocious manners, airs of superiority and righteousness and constant criticism of everyone else is a trial to those about him but also an indication that he is a trial to himself. Much of this behavior is *overcompensation* and excessive assertiveness to bolster his feelings of uncertainty and inadequacy as rapid physical and emotional changes are occurring within him. Parents need reminding they were once quite as difficult, and that they should extend to the adolescent tolerance,

not ridicule, patience, not instability, and leniency, not annoyed discipline. By their wise handling of the adolescent, they can minimize the resentment and rebellion too commonly found in this period of life. They can foster his social adjustment by acting as sympathetic counselors, not as meddlers or dictators.¹²

Garland¹³ makes the following comments:

Restrained and inarticulate, the adolescent no longer reveals his innermost thoughts at home and thus fails to benefit from the safety valve of a confidential relationship with the parent. The parents have also their reticences. The father, even if he recognizes the desirability of it, cannot talk to this strapping and somewhat arrogant youth as that individual needs to be talked to, nor can the mother approach the daughter according to her needs.

The adolescent needs some kind of adult companionship that is free from family inhibitions. "It may frequently be the physician who can best serve as parent substitute, and particularly the pediatrician, if he has dealt wisely with his patients during their childhood. In this terra nova of medical interest he has early staked his claim."¹⁴ Parents may make the adolescent worse by dominating and overprotecting him; regardless of whether their children find them interesting or boring, companionable or indifferent, just or unjust, sooner or later the children will and should leave home.

Sex education should have been taken care of by the parents during the childhood years, but it is a wise rule to get from the adolescent his ideas on anatomy, physiology, coitus, pregnancy, childbirth and venereal disease. One should question closely but gently and should not be fooled by what is usually a superficial knowledge given in glib answers, for the investigator is frequently amazed at the half truths and gross ignorance of the adolescent, who depends on street talk for his sex education. A frank discussion of sex opens the way to a calm introduction of the often highly emotionally charged topic of masturbation, and provides an excellent opportunity to desensitize the adolescent on this matter. If the parents bring to the office an adolescent with a history of troubles about masturbation or what seems to be a homosexual situation, a safe and effective way to introduce the material is to tell the patient that when his parents were young anything about sex was considered scandalous, and that many parents get upset about such things and exaggerate them. As a rule, this approach makes the adolescent realize immediately that the physician is not the usual critical adult but an understanding person who does not automatically condemn him as an outcast or abnormal. The homosexual situation is usually found to be a harmless crush on an older person of the same sex, although the relation may

have been prolonged unwisely. If the adolescent has been caught in a homosexual act, he and the parents should be told that it is only a carry-over of sex curiosity and experimentation from childhood or a substitute expression of sex drive in a person whose sexual maturity has not yet reached an adult heterosexual stage. If the homosexual behavior persists or the adolescent is definitely effeminate—or masculine if the patient is a girl—in appearance and manner, he should be referred to a psychiatrist.

The most obvious obstacle during adolescence is the acquisition of heterosexual stability. It is in sexual matters that one has the most difficulty in getting an adequate history from the patient; it is a subject requiring great tact and patience, particularly with girls, and the information is often unobtainable until the emotional retention results in an explosion in a panic reaction or in a hysterical episode. Despite the so-called "frankness" of modern youth, the adolescent is often reluctant to admit that he is troubled about sexual matters. Thom¹² states, "By the time the psychiatrist sees the adolescent who is having conflicts over sex, the situation has usually become involved and invariably there has been considerable elaboration of incidents which in themselves were not particularly important." The family physician can head off the development of such conflicts if he is alert and able to devise means to have the adolescent come to him spontaneously and early in the trouble.

The stages that a person passes through before reaching healthy adult heterosexual development are as follows: an interest primarily in himself, accompanied by self-exploration and resulting in autoerotic practices common to all infants and young children; an interest in the differences between sexes, with some indiscriminate sex play and no preference for a particular sex, characteristic of childhood; an interest primarily in those of the same sex, characterized by "crushes" and hero worship, together with antagonism toward the opposite sex—these attitudes are found in early adolescence; and finally, in mid-adolescence, an interest in the opposite sex begins as "puppy love" and proceeds through late adolescence to adult heterosexual maturity.

The crushes and hero worship of early adolescence are evidences of transient homosexuality, which is unconscious and normal and seldom reaches overt expression, or of experimentation, if such activity occurs. When "puppy love" appears, the adolescent is usually well on his way to successful heterosexual adjustment. Should the unconscious homosexual stage be prolonged beyond the age of eighteen, some investigation is indicated, since superficial causes, such as inability to dance,

fancied or actual ugliness of face or body and lack of suitable clothes, may be keeping the heterosexually inclined adolescent from taking the plunge into the social affairs necessary for contacts with the opposite sex. Aldrich and Aldrich¹⁵ write as follows:

If it were possible to keep to the perfect letter of our social regulations, youth would grow up without experiencing any sexual feeling at all until marriage, at which time they would be expected to adjust successfully to this complicated growth process . . . when the maturing child feels the normal quickening of his sexual life, memories of those early punishments (shamings and spankings for childhood sex play) come up to make him feel ashamed and guilty instead of giving him a basis for security and satisfaction in the growth of his ripening powers. An appreciation of sexual competency as a constructive asset is a high and difficult standard for children to attain in our inconsistent world.

Career ambition needs attention, not just actually to pick out the best suited for the particular adolescent but also to keep him interested in the future along with a reasonable amount of self-evaluation (physique, intelligence, any unusual ability, education, maturity and so forth) to keep at a minimum the wild selection of impractical careers so common in early adolescence. It is useless directly to dissuade the adolescent from a certain career goal, no matter how absurd or impossible it may be; however, by reviewing with him his assets and liabilities in reference to the desired goal and encouraging him to investigate the years of training needed, one can often get him to abandon or modify his immature ambition. Equally important is the procedure of leading him into serious and mature planning for his career selection when such a selection is in keeping with his abilities. The adolescent with average intelligence should take a high-school course that will be useful in office work and the trades, and should not spend his time on the classics of a college preparatory course and be left on graduation day with much impractical knowledge so far as getting a job in everyday life is concerned. One should impress on him the value of night school to further his education while he is supporting himself. Jobless youths are serious problems, and it requires real ingenuity to devise and find ways to keep these young folks occupied, to prevent delinquency and loss of self-respect. They should be urged to do charity work, attend almost any of the free courses that most cities offer, or investigate the NYA and CCC projects, as well as military service—anything to keep them busy. Many parents, and consequently their children, still have caste ideas concerning the "trades" in contrast to white-collar jobs, and may ignore valuable advice about the study of a trade.

Delinquency refers to antisocial behavior that is considered criminal, such as habitual stealing, destruction of property, vagabondage and running away, occurring in children under the age of sixteen in most states. As mentioned above, genuine psychopaths, of which true juvenile delinquents are but smaller editions, are very serious problems and should be referred to the psychiatrist.¹⁰ Meanwhile, there is too great a tendency to label as a juvenile delinquent any youngster picked up by the police more than once. Too often, the child or adolescent has against him several minor charges that are reflections of obviously unhealthy environment—slum sections, broken homes, idleness, poverty—rather than vicious antisocial behavior from character defects. Thom¹¹ concisely outlines modern thought and trends concerning delinquency, and indicates the value of mental hygiene. "I believe that until mental hygiene can be reduced to such terms that it can be utilized in the everyday practice of parent, teacher, nurse, physician, probation officer and others concerned with the training and education of children, it will not serve a useful purpose. . . . Much so-called 'delinquency' needs only careful analysis of motives, the offsetting of such etiologic factors as poverty, disease and idleness, and the redirection of the adolescent into healthy activities (clubs, camps, sports, hobbies and recreation) under mature guidance of counselors, playground directors, Big Brothers' and 'Big Sisters,' or similar mentors. Healy and Bronner¹² have reported most encouraging results in a series of 400 cases treated at the Judge Baker Guidance Clinic five to eight years before the follow up survey. They record 81 per cent favorable results in nondelinquents,—that is, children with the less severe personality and behavior problems,—and 70 per cent favorable results in delinquents.

Feelings of inferiority may be inferred from the adolescent's behavior (aggressiveness, noisy conduct, shyness and aloofness), or the cause may be described by him as frail body, clumsiness, stupidity, inability to dance, acne, inadequate clothes and so forth. Each point can be handled by explanation, by reassurance and, particularly, by a reference to similar difficulties endured by other adolescents. Adolescents are often sensitive to wearing secondhand clothes, and should be allowed some new ones occasionally, at least the 'Sunday best' outfit should not be a castoff. Often, the social and economic levels of the family may be sensitive points as the adolescent compares them with those of his friends and acquaintances. He may resent or feel ashamed of what he considers a class inferiority because of such factors as car, clothes, church affiliations, portion of town in which he lives, size of house and whether rented or owned, size of

allowance, and social status as shown by clubs and societies in which his parents may or may not hold memberships. He should be desensitized to avoid snobbery, and the reading of appropriate biographies will promote a realistic sense of values.

Chronic invalidism or prolonged convalescence, as in acute or severe chronic rheumatic fever, pulmonary or bone tuberculosis, anterior poliomyelitis, chronic pyogenic osteomyelitis and amputations, presents a crying need for mental hygiene precepts and psychotherapy. The ingenuity and patience of the physician are often taxed to keep these adolescents occupied, interested in daily life, cheerful, unselfish and free from self pity. An attitude of gently humorous interest in their case and encouragement to follow several practical activities or hobbies will sustain these young folks for months. In the community, facilities may be available for interesting and instructive 'visiting services,' such as social work, teaching, occupational therapy and voluntary reading and games with invalids. At times, it may be necessary to advise care in a foster home¹³ because of crowding or a severe personality clash between the invalid adolescent and some member of the household.

Consultation with the school authorities may be advisable when behavior or scholastic difficulties beset the patient. Again, one must use tact and often secrecy in such contacts, otherwise, the adolescent may believe that the physician is violating his confidence or is siding with the school. When the necessary history has been obtained from the school officials and the problems outlined, the physician should recommend indicated changes in school curriculum, suitable disciplinary methods and his own general plan for handling the situation directly with the patient.

In conference with the school authorities, one can often profitably suggest inclusion of sex education material¹⁴ in courses, such as biology, physiology, hygiene, physical education, sports and sociology. Personality clashes between teacher and adolescent should not be taken seriously provided investigation does not show the teacher to be a misfit. The adolescent must be quietly impressed with the reality that all through his life he will be under the authority of apparently disagreeable persons and must learn to 'take it', in addition, he should realize that the personal problems of the teacher, such as financial worries, emotional disturbances, family stresses, and physical and nervous fatigue, may be solely responsible for the irritability and antagonism he shows the adolescent. Teachers²¹⁻²³ notoriously consider the relatively aggressive child a behavior problem because of his nuisance value, whereas the shy, withdrawn child is praised. Unfortunately the former is by far the healthier personality. As pointed out above,

regarding the parents, it is often not the adolescent who needs all the guidance and correction: those in contact with him need considerable education in mental hygiene.

Marriage of an adolescent does not automatically make him an adult, no matter what the legal attitude may be. If the marriage is permitted to continue, both the adolescent or adolescents and the parents need help to smooth the personality adjustments necessary, particularly when there has been an elopement. The adolescents are grateful for advice concerning special adjustment and the question of pregnancy, and many nonmedical problems, such as living with parents, whether both adolescents should work, life insurance, and even budgeting and homemaking. In turn, the parents need desensitization to their "in-laws," and often must be restrained from seeking legal redress or disowning the adolescent when such actions solve nothing and only make the situation worse. Unfortunately, the physician's influence is seldom sought in such matters.

Contact with pornographic literature, a common experience in adolescence, varies from crude sketches and verses on sidewalks and toilet walls to "French postcards" and lewd cartoon books. That this is not a more serious problem is a compliment to the adolescent, or perhaps it is because he is desensitized by the prevalence of sex appeal in modern motion pictures, magazines and advertisements. The more overt occurrences respond to matter-of-fact discussion with those involved; one appeals frankly to reasonable standards of personal ethics and good taste, and makes specific efforts to locate and deal adequately with the adults who are supplying such material to the adolescents. Making a humiliating example of such youthful offenders or preaching with righteous indignation does little good.²⁴

Dishonesty, including lying, cheating in examinations and stealing, should be handled in a similar manner. The motives for such conduct, of course, are important, since etiologic treatment is always best. Cheating may be based on attempts to maintain high grades or pass in school subjects demanded by parental ambition, or may be prompted by laziness or boredom. Stealing may be a means to obtain desired luxuries or money to buy favors and win attention from associates when inferiority or handicaps prevent satisfactory competition otherwise.

Since the adolescent must learn to adjust himself in community life, every possible community faculty should be employed to interest him and occupy his energies. Thus, the physician should keep in mind the availability of clubs, training projects, hobby groups and so forth.

Concerning psychotherapy in general, the following realistic evaluation of Kanner²⁵ is pertinent:

For psychotherapy, regardless of dictionary definitions, is not a sectional procedure, a trick, a technique, or circumscribed method, a selected emphasis addressed to an unconscious, a complex or any other personified abstraction. Practical psychotherapy is the organized treatment of a person in trouble, uniquely adapted and readapted to a unique person and a unique situation. . . . Its ideal goal is the adjustment of all that is maladjusted in an individual child and his specific environment; its working endeavor is the adjustment of all that can be adjusted at a given moment. It steers clear both of Pollyanna sweetness and nihilistic bitterness. . . .

CASE HISTORIES

CASE 1. C. D. F., a 19-year-old boy, reluctantly went to a psychiatrist with a complaint of constant fatigue and lack of energy. He was well developed and nourished, and had the physique of a football player. He left college in the second year to go to work, and had his own used-car business on a small scale but made a fair living. His complaints of fatigue, lack of energy and aching all over had been in evidence for years, and he did not recall ever feeling "pepped up." There were no hypochondriacal complaints, and he was humorously aware of the discrepancy between the complaint of fatigue and his strong physique. The history showed an extremely dominating, querulous, attention-craving father who was very successful in business, but who was a mass of hypochondriacal complaints and spent two or three months each year going from one health resort to another. The mother, an unusually pleasant person, understood the father and tried to offset the terrific tension that his presence constantly maintained in the household. This tension was so severe that the patient's younger brother (Case 2) also required psychiatric help. An older brother, after years of clashing with the father, had left home, and during 3 rather stormy years of trying to get settled with a job and a wife, had also needed psychiatric help. The patient had never taken an active interest in sports and never did much physical work. The social adjustment was good with adults but only fair with his colleagues, since his constant feeling of fatigue made it an effort to take part in dancing parties, swimming parties, picnics and so forth.

Treatment consisted in an insistence on a gradually increasing program of physical activity, including a Y. M. C. A. membership and joining a hiking club, which took the patient on cross-country hikes and amateur mountain climbing at least twice a month. The effect of his father's personality was explained, and the patient saw for the first time the whole situation so far as intra-family attitudes were concerned. With this insight, he said: "I think we are all fighting against the old man. He never went to college but has always said that he would give his boys a college education. As a matter of fact every darned one of us [3 boys, aged 24, 19 and 18] have quit college despite the old man's objections." This was exactly what had happened; the only son who had completely rebelled was the oldest, who had left home.

CASE 2. D. R. F., an 18-year-old boy who was referred to the psychiatrist by his brother, C. D. F. (Case 1), was a slender, restless, obviously tense boy who talked rapidly. His story concerning the father's influence on the children

was essentially the same as that given by his brother, but he added: The old man gets me down more than the others now, probably because I am the youngest. I am high strung like he is anyway, and he nags and criticizes me so much that I feel just no good.

The patient worked during the summer in a small store owned by the father, and enjoyed meeting people and serving them. Such work had given him a sense of self confidence and made him feel useful. The father in the meantime, regarded keeping the boy a clerk in the store as excellent discipline. The patient recognized this motive and was somewhat amused by the fact that instead of being disciplined and under the control of the father he was actually in the best environment to get away from the constant feeling of insecurity that his father's influence thrust on him. The patient said that he was entering the second year of college but really wanted to go to work in some business in which he would have contact with people and give service. He stated that he was going to leave college about Christmas time, although he dreaded the scenes his father would put on when he heard the news. His next words were practically an exact quotation of what his brother had said during an interview: that the father felt inferior at not having gone to college and was obsessed with the idea of giving his children college educations.

From what his brother had been told the patient had developed insight into his own nervousness and treatment consisted chiefly in more explanation and a great deal of reassurance.

CASE 3 H L A 16-year-old girl was referred by a dermatologist after he had been told by the parents that the girl seemed very depressed. He was treating her for marked acne vulgaris of the face, neck and shoulders and she had been referred to him by the family physician whose efforts for several months had not helped the skin condition. The patient was very well developed and nourished with good facial features, except that her nose was somewhat flattened. Posture was good and her carriage in walking was unusually good. There was marked acne over the face with many areas of folliculitis and a moderate degree of scarring. She was in the junior year of high school and had active interests in basketball, dramatics and church activities. She did not care for dancing and had not yet had any special love interests.

The patient admitted that her feelings of depression were due to sensitivity concerning her complexion. She frequently noticed people looking at her because of her skin condition and the boys and girls at school sometimes teased her. She often cried to herself particularly at night and although she did not avoid group social contacts she did not seek any more than went along with her school and church activities. She definitely avoided dates with boys.

Treatment consisted of reassurance and explanations for the acne. The patient was informed that glandular overactivity, which is so common during the adolescent period, was responsible and that the lesions would eventually regress. She was desensitized against awareness of people looking at her by the statement that her excellence of figure, carriage and poise were probably as much responsible for people noticing her as her poor complexion. It was suggested that her disinterest in dancing was based as much on her awareness of being a poor dancer as it was on her sensitivity about her face. She was advised to use every opportunity to dance and the parents made arrangements for her to take lessons in ballroom dancing. Her life situation was formulated as follows. Since she

was interested in business and secretarial work, and for the next 3 years her main job would be to finish high school and get a year of business college, she should point her main efforts in this direction. In the meantime she was to improve her dancing and constantly keep in mind that despite her temporarily poor complexion, her assets of physical attractiveness were unusually good and that a year or so later, when her skin condition had subsided she would be a very pretty if not beautiful girl. Incidentally, she was reassured by the psychiatrist and the dermatologist that whatever scarring remained could be removed by plastic surgery.

This particular case was properly handled all along the line although the family physician was somewhat slow in referring the case to the dermatologist. The most important points in the psychotherapy were that the skin condition was an annoying human experience and that the patient's physical attractiveness and personality were definitely superior and would not be particularly impaired by the facial blemish.

CASE 4 N C An 18-year-old girl, had had practically constant nausea and frequent bouts of vomiting for 3 years beginning shortly before an uncomplicated appendectomy. She had a brother 2 years her junior who was in the same class in school and there was a good deal of rivalry between them. The patient's symptoms of nausea and vomiting were always aggravated by any change, such as that caused by visitors and trips. Once or twice she had fainting episodes in school. For the previous 2 years, she had done practically nothing except go to school. She was waited on by her parents and was not even required to pick up her own clothes. Examination showed a very well developed and well nourished girl who was emotionally quite immature and talked and acted like a high school freshman.

After the nervous origin of the nausea and vomiting had been explained a program was outlined with the parents in which the girl was to assume an increasing number of duties and responsibilities about the home. She was made to care for her own room, do ordinary sewing, get breakfast and plan the other meals, and do all the marketing. There was no open rebellion at these tasks probably because it was explained that she would not be permitted to enter college—where she had already been accepted—if she did not follow directions in detail. Within a month on such a program there was a marked change in her general poise, the chatter and juvenile restlessness of the usual 14-year-old which had been her general behavior faded into the appearance of a fairly quiet and more or less serious girl of 18. She was beginning to take pride in the household responsibilities, experimented with new menus and had done some original and inexpensive interior decorating in her own room. The symptoms of almost daily nausea and vomiting were quite stubborn and it was another month before any particular change was noted. These symptoms slowly subsided within the next 6 months and now occur only once in 2 or 3 weeks.

CASE 5 G J A 19-year-old boy, was oversensitive and oversolicitous concerning his health. Limited exercise to avoid fatigue went to bed early each night to get at least 10 hours of sleep, was fussy about his diet and ate various types of popular health foods. Throughout high school he had frequent bouts of vomiting for which an organic basis was never found despite repeated examinations. The history of the vomiting spells showed definite association with nervous tension and a feeling of inferiority to his fellow students both scholastically and so-

cially. He did well in his studies in his freshman year at college, and during the first half of the year there were no spells of vomiting. As the year progressed, however, the vomiting returned, and during the summer vacation, the family physician, concluding that the vomiting was functionally related to the school situation, recommended that the patient travel or work for a year and then return to school. The diagnosis was only partially right, since after the first few weeks of an office job, the vomiting returned, and the family physician referred the patient to a psychiatrist. Another symptom, insomnia, had developed, and in addition to his overconcern with his physical health, the patient felt he would lose his mind because he was not obtaining adequate sleep.

He had been reared on a farm, the youngest of four boys; the oldest brother had taken charge of the farm at the father's death. The other brothers imposed on the patient by giving him much more work and responsibility than his years warranted because he was very faithful, being the first one up in the morning and the last one to retire at night. He had therefore practically no normal late childhood and early adolescence from the standpoint of carefree play. The case was thoroughly reviewed with the family physician, and a program of psychotherapy and occupational therapy outlined. The chief points in psychotherapy consisted in reassurance about his health and particularly about the problem of sleep, and in the development of an insight regarding his excess of seriousness, conscientiousness, health consciousness, reserved attitude and self-criticism. Occupational therapy was directed toward hobbies of the group type, to foster social ease. After several months of membership in a hiking club and a photography club, the patient made several valuable friendships and acquired self-confidence in social situations. In the 2nd month of treatment (an hour interview once a week), the vomiting ceased and sleep improved; at the same time, he found his office job much less irksome. He returned to college and has made a very satisfactory adjustment; he is still inclined to be rather shy and a bit overcareful concerning his physical welfare, but his original condition is much improved.

CASE 6. R. S., a 20-year-old high-school graduate, had been married for 2 years and had 1 child (aged 18 months). At the age of 14, this boy lost his left arm at the shoulder from an automobile accident. He was the older of 2 children and was always the mother's favorite; his disability increased the amount of attention from her, so that he became spoiled, sulky, demanding and self-pitying. He took no part in sports or hobbies; his parents gave him a car and plenty of money, and most of his time was spent on parties, drinking and racing around the countryside. His girl friends were of an inferior type socially and intellectually, obviously because he felt more comfortable in their presence and because his money and his car made a great impression. He eventually had to marry a girl because of pregnancy; she had only a sixth-grade education and worked as a waitress at a very inferior type of tavern. The boy's parents, after this episode, were amenable to reason, and realized that their oversolicitude had been to a great extent responsible for the boy's warped personality. He had never been taught to compensate for his physical handicap. The parents accepted the girl and at first had the couple live with them, but after the baby came they very wisely set them up in a home of their own.

The boy is still far from well adjusted but is trying to accept advice and responsibilities. Treatment consisted of explanation, reassurance, praise and criticism carefully

blended, and a definite program of work, social contacts, hobbies and a continuation of his and his wife's education through planned reading and night school.

CASE 7. H. C., an 18-year-old college freshman, had been getting drunk about once a month since the age of 15 and had been dismissed from two preparatory schools because of his drinking. He was very reserved and found that alcohol made him able to mix socially with comfort. He was the youngest of 4 children, all boys, and there was 8 years between him and the next older brother. The father was a West Point graduate, domineering, aggressive and a very successful businessman. There was considerable army tradition in the family; several ancestors and a brother were West Point graduates. The boy qualified for West Point and passed the entrance examinations, but was turned down because of defective vision. This was a great disappointment to him and also to his parents. The mother was a vivacious, attractive woman, of Spanish ancestry, and temperamentally the opposite of her husband; she had spoiled the boy in her efforts to soften the father's treatment of him. The college authorities had noted a gradual decrease in efficiency, withdrawal from social contacts and a facial expression of depression. The college physician found nothing organically wrong and entirely missed the psychiatric implications, so that the boy was sent home with a medical opinion suggesting that he was lazy and needed disciplining. This, of course, only made the father's attitude severer, and for a while he kept the boy home studying; as a result, the patient became more and more withdrawn and depressed. On two occasions, there was suggestive evidence that he had made suicidal attempts—the first by an overdose of codeine, and the second by illuminating gas. The boy would not admit these, but the mother was sufficiently alarmed to refer him to a psychiatrist.

The history given to the psychiatrist was almost classically that of a slowly developing schizophrenia, and the prognosis appeared poor. On examination, however, the psychiatrist noted that the boy, although appearing disinterested and apathetic, within a relatively short time made a very active transference to the physician and soon poured out his story. Another factor that made the prognosis much more hopeful and entirely changed the diagnosis was the significant observation by an attendant caring for the boy at home that when the parents were out of the house for several hours the patient turned on the radio, at times hummed or whistled in an alert, buoyant manner, and occasionally laughed quite cheerfully. At no time was there any evidence that this boy was malingering; it seemed that the father's presence was a dark cloud, which immediately overshadowed the boy's usual state of average adolescent spirits.

The boy gave the following story to the psychiatrist: "For a year and a half, I have lost all interest in things [the West Point disappointment occurred at about the time of the onset]. I had no more emotional reactions to anything. In college, I studied hard but gradually my concentration got worse. One night I spent from 8 p.m. to 4 a.m. going over one or two paragraphs without being able to understand or remember the contents [his marks in preparatory school had always been high and he had a superior intelligence]; this scared me. I quit school and went home by hitch hiking, but got drunk on the way [in a little town near his home, as though he sought alcoholic courage before facing his parents] and spent a night in jail. My father raised hell; he made me stay in all the time and study. He wouldn't let me see my girl

[the patient was in the middle of an intense love affair, of the usual idealistic, adolescent 'puppy love' variety], and I worried about another fellow taking her out. All I do is hang around the house, usually in my room. I don't care to see anyone, and I don't want to do anything but read or sleep." There were no hallucinations or delusions, ideas of reference or feelings of being controlled.

Therapy in this case was difficult and not very successful at first because he was kept at home. The parents tried to be co-operative, but the father considered the boy's symptoms "all a bunch of damned foolishness—all that boy needs is a few good beatings." The boy was given a great deal of freedom, the relaxation of restrictions at first seemed to help him, but he soon became quite reckless in behavior, winding up in jail for drunken driving. It was apparent that a return to personal freedom should be made more slowly and in a neutral environment, and he was therefore sent to a private sanatorium. It was subsequently learned that although the father gave the boy the freedom recommended by the psychiatrist he stood in the background and constantly glared his disapproval of the boy's actions and often muttered threats and curses under his breath. This attitude, of course, only made the patient more and more panicky, increasing his recklessness as he tried to get in as much fun as possible before the father clamped down on him again. The boy's adjustment in the sanatorium was excellent, and he rapidly developed insight into the emotional turmoil in which he had lived for about 2 years. After 6 months he returned home to approximately the same parental situation, but he was able to withstand the father without an open clash and also without building up a store of resentment. He re-entered college and is successfully completing his freshman year. It is quite possible that the 6 months of hospital care would have been unnecessary if the college physician had been able to get the boy's confidence and learn the whole story or had recognized that the boy was in an emotional turmoil and referred him to a psychiatrist.

CONCLUSIONS

An analysis of the problems of adolescence is presented, methods of psychotherapy are outlined, and appropriate case histories are discussed.

The adolescent must gain independence and freedom from parents; he must learn to take re-

sponsibility for himself and to some extent for others; he must learn the value of money; he must learn to live with others, to make a comfortable social adjustment and to respect the rights of others; and he must have a reasonable goal of successful adulthood regarding education, economic stability and psychosexual maturity.

Adolescents with chronic illnesses or crippling physical defects are especially in need of psychotherapeutic attention.

Erratum. In the paper "Deterioration of Milk by Bacterial Growth Under Refrigeration at 40°F," by Frank E Mott and Henry Mazur, in the July 30 issue of the *Journal*, three errors appear on page 174: the abbreviation "C" in line 21, column 2, and in the two subheadings in Table 2, should be changed to "F."

MEDICAL PROGRESS

KIDNEY DISEASE

REGINALD FITZ, M.D.*

BOSTON

TWO excellent reports on recent medical progress as it concerns renal disease have already been published in this year's series; both are by Dr. John H. Talbott,^{1,2} of the Massachusetts General Hospital. In one, he discusses modern tests for renal function and describes methods now being employed to investigate glomerular filtration and effective renal blood flow. To read of Diodrast and inulin clearance tests as they are now employed makes older clinicians like myself a trifle nostalgic. Thirty years ago, I spent the summer in Tübingen, working with Carl Schlayer. His researches were pointed in the direction of studying tubular and glomerular function, as a test for the one potassium iodide clearance, and for the other, lactose clearance being used. Smith³ has now gone ahead much farther along this line, adopting for the same purpose a different iodine compound and a different sugar. His methods are being tried in different clinics and appear to offer interesting results. As an example of the kind of work going on with these methods, Dill, Isenhour, Cadden and Schaffer⁴ have studied renal blood flow in the toxemias of pregnancy, concluding that the same fundamental vascular abnormality is responsible for hypertensive disease as for toxemia.

There is still debate regarding how much the rate of blood flow through the kidney is impaired by hypertension per se. Dock⁵ has attempted to explore this angle of the renal problem by perfusion experiments. He believes that kidneys from patients with hypertension have vascular beds that are within the range of normal and that therefore renal arteriosclerosis is rarely a cause of hypertension, although he admits that this may be a secondary complication.

Talbott's second paper discusses what he terms "heterogeneous renal disorders." He describes a variety of unusual renal disorders that are of considerable interest to the man who may be more concerned with the clinical side of nephritis than with renal physiology.

The war has already brought to light two forms of kidney disease that have hitherto received no great attention. Gilligan and Blumgart⁶ have dis-

cussed what is termed "march hemoglobinuria." This medical curiosity, no doubt, occurs much more frequently than is generally believed.

Nine years ago a patient of mine, hitherto always able to exert himself without trouble, suddenly developed what appeared to be bloody urine after playing a game of squash. A few days later, the hematuria recurred under the same circumstances, and the patient consequently gave up such a violent form of exercise. Some time later, however, after a gentle outdoor run, he developed a third attack of what seemed to be painless hematuria. Complete urologic studies, including cystoscopy and retrograde pyelography, were made, with completely negative results. Since then, the patient has played golf and mixed double as he chose, with complete impunity. Many specimens of urine have been examined, and they always have been entirely normal. I suspect that the patient had an attack of so-called "march hemoglobinuria."

Gilligan and Blumgart have made an excellent clinical study of 3 such cases. Their article is worth reading not only for its informative value but also for the delightful manner in which it is presented. Briefly, the 3 cases were studied most meticulously in a variety of ways. The authors conclude that march hemoglobinuria is a form of paroxysmal hemoglobinuria already well described. It occurs in attacks in otherwise healthy persons, follows walking or running, and may have something to do with the mechanics of body posture. There are usually no symptoms or very slight symptoms with attacks. The paroxysms appear to be due to intravascular blood destruction rather than to any extrinsic cause, and no great amount of blood is destroyed at any one time. Spontaneous recovery is the rule.

This study has been presented at a very opportune time. Gilligan and Blumgart predict that this type of paroxysmal hemoglobinuria will soon attract much more attention than ever before because of the large number of young men who are engaged in the strenuous exertion of military training. During the next few months, therefore, other cases will doubtless be presented. The value of having the condition in mind and of differentiating it from more serious conditions leading to the passage of blood-colored urine is obvious.

In the *British Medical Journal*, two interesting papers^{7,8} described the peculiar renal changes that complicate severe crushing injuries. People so injured are likely to develop, in the course of a few days, a very striking renal lesion characterized

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, Vol. III, 1942* (Springfield, Illinois: Charles C Thomas Company, 1942. \$5.00).

*Lecturer on the history of medicine, Harvard Medical School.

clinically by generalized edema, oliguria, acidosis, a rise in the blood urea nitrogen, a retention of blood phosphorus and potassium and a fall in blood sodium and calcium. The prognosis is always uncertain. The fatal cases that have been examined have shown a degenerative lesion localized chiefly to the collecting tubules and not unlike the type of acute nephritis that may develop after improperly matched blood transfusions.

Knowledge concerning this disorder has developed very quickly. In the first place, as so often is true when something new in medicine appears to be uncovered, the condition has already been fairly well studied. It seems ironical that Minami,⁹ in 1923, who seemingly was then a Japanese student working in Pick's laboratory in Berlin, should have been the first to publish a comprehensive review of the subject. It is clear, however, from this paper that during World War I the Germans were thoroughly familiar with the peculiar syndrome that may follow crushing injuries, although why no attention was paid to the matter by American and British officers is less certain.

During the present war, the British have again been impressed with the crush syndrome, and, through the use of methods that were not available to previous workers, have added much to knowledge concerning it. Several hypotheses regarding its cause have been presented. Robertson and Mathews¹⁰ have given an explanation that now is generally accepted: a crushing accident interferes with the circulation in the affected parts, and there is considerable muscle damage. A substance called 'myohemoglobin' is set free, is absorbed in to the general circulation, and passes to the kidney. Glomerular activity is reduced by this foreign substance, and tubular flow is diminished. As a result, myohemoglobin is concentrated in the tubules, with the formation of casts. Thus, it seems probable that acute nephritis from crushing is due to mechanical obstruction by myohemoglobin and also, probably, to some other unidentified toxic substances that are formed.

Several forms of treatment have been developed. On the theory that the syndrome is due not only to the liberation of toxins from the crushed tissues but also, in part, to loss of blood constituents into the injured limbs, treatment with intermittent positive pressure has been attempted. The treatment of the infection or the gangrene that so often accompanies the crush has also been attempted by the use of various more or less radical surgical procedures on the theory that pressure in deep and badly injured muscle compartments may add to the damage to tissues. Alkalization and the intravenous injection of fluids in various forms—including, most recently, glucose in isotonic sodium sulfate solution—have been advocated.

Adrenocortical hormone has been administered because of the high blood potassium levels frequently encountered. Of course, transfusion with whole blood, serum or plasma has often been used. The crush syndrome is so serious and its mortality is so high that careful clinical or experimental studies dealing with it may prove to be extremely valuable.

I can recall once having seen a patient in the Peter Bent Brigham Hospital whose legs were badly crushed in an automobile accident. I suspect that he developed the form of renal lesion that now so much interests the British medical officers for within 48 hours after the accident and for no apparent cause, the blood urea nitrogen was 61 mg per 100 cc.

The patient developed a gas-bacillus infection lost both legs and later required an indolent intractable anemia, which lasted for several weeks, a finding said to be characteristic of the crush syndrome. He is now alive and well.

Detailed reports of similar cases more carefully studied in civilian hospitals would be helpful in developing better methods for the treatment of this type of casualty. Unfortunately, so long as the war continues, the syndrome is likely to be encountered often, and certainly, as judged by the British experience up to date, it is serious. Husfeldt and Bjerring¹¹ have demonstrated that civilian hospitals afford a chance to study a problem of this nature. A few cases carefully observed in the tranquil atmosphere of civil life might prove enlightening, and surely the problem of injury from crushing can be investigated in the laboratory by direct experimentation.

So far as the peacetime aspects of renal disease are concerned, the literature of the past year, as usual, contains many interesting articles. If one wishes to get a bird's eye view of what surgeons are doing in the treatment of cardiorenal disease, a paper by deTakats et al.¹² is worth reading. Hypertension in certain cases can now be approached through surgery, provided that the correct diagnosis of the underlying cause is first established. Certain unilateral adrenal tumors, for example, may cause paroxysmal hypertension, the removal of a unilateral atrophic kidney also affords a means of curing hypertension in a strikingly dramatic fashion, attempts to revascularize the kidney by tissue implants appear to offer some hope of success, and even the treatment of hypertension by splanchnic nerve resection is still under discussion.

Someone¹³ has published a very interesting paper, which deals with the intelligent use of fluids in the care of men with impaired renal function due to prostatic obstruction. He points out clearly how essential the proper use of fluids is, and he comments on the various changes in the blood chemical findings that may occur. If these changes are interpreted correctly, they help to point out the type of fluid that should be administered and also

indicate the results of the therapy that is being pursued. This is a well-written, clear and comprehensive paper.

Endocrinologists have begun to study the kidney seriously. Selye¹⁴ has given an excellent review of the literature in this field and has added some experimental evidence of his own. He thinks it probable that the kidney is dependent for the maintenance of its normal structure on the balanced production of the growth and thyrotropic principles in addition to the effect of gonadotropic and adrenotropic hormones. Selye's paper is interesting to read, for if results obtained experimentally can be transferred to the clinic, it is easy to imagine many endocrinologic implications that might play a part in causing different forms of kidney disease.

To one who has heard the subject of nephrosis debated, a paper by Gilbert¹⁵ is refreshing. As is well known, there are two schools of thought: one is that nephrosis is a separate entity from which patients either recover or during which they die of intercurrent infection; and the other is that nephrosis represents simply a stage in development of the pathologic process that ends in clinical and anatomic chronic glomerulonephritis. Those who worked under Dr. Henry A. Christian have absorbed the latter belief. Gilbert reports a typical case of nephrosis, observed carefully during a four-year period, in which the pathologic findings characteristic of chronic glomerulonephritis were finally demonstrated.

It seems interesting, too, that the much debated topic of the effect on hypertension of a high-protein diet should still be worthy of investigation. Yet Philipsborn, Katz and Rodbard¹⁶ have once again demonstrated, this time on dogs, that these diets have no particular effect on the course of hypertension, although, of course, such diets may elevate the nonprotein elements of the blood nitrogen. At the moment, medical fashion appears to be in a phase of the cycle that is very far away from that of those days when the patient with hypertension was told, at all costs, to eat neither meat nor salt.

Anyone who has recognized hyperparathyroidism and has had the satisfaction of seeing a parathyroid adenoma removed will forever after maintain an interest in the intricacies of calcium metabolism. Andersen and Schlesinger¹⁷ have described 2 new cases of renal hyperparathyroidism and summarized current views on this subject. They make the point that there is a difference in secondary hyperparathyroidism from kidney disease as it is seen in children and adults. In young persons, the underlying renal lesion is likely to be congenital, whereas in the adult it may be acquired and the result of pyelonephritis, glomerulo-

nephritis or vascular disease. At all ages, the accompanying renal insufficiency is severe and chronic. At any age, in renal hyperparathyroidism, a moderate excess of vitamin D, at levels usually harmless, may produce hypercalcification of the bones and deposition of calcium in the tissues, including the media of the small arteries.

Besides its interest, another useful aspect of this paper is its bibliography. References are given to the first account of extirpation of a parathyroid adenoma as a means of treating osteitis fibrosa, to the literature dealing with hypertrophy of the parathyroid gland secondary to chronic renal insufficiency and, finally, to articles dealing with the close similarity between adult renal hyperparathyroidism and renal rickets.

* * *

As I have stated in previous years, I find it extremely difficult to write anything that approaches a complete report of current literature during a given interval on such an inclusive subject as renal disease. I have made no mention of the work going on with renin, on the effect of the sulfa drugs on the kidney or on many other aspects of kidney disease. Rather, I have tried to limit myself to comments on work, either old or new, that during the past twelve months has been of especial interest to my own tastes.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28331

PRESENTATION OF CASE

A sixty-five-year-old man was admitted to the hospital because of jaundice.

The patient had been well until seven weeks before admission, when he had a so-called "streptococcal throat" for a week. During this episode, he received a twenty-four-hour course of sulfanilamide. He never fully recovered his strength and, three weeks prior to admission, noted for the first time the onset of painless jaundice accompanied by light stools and dark urine. The degree of jaundice did not seem to fluctuate, and during the two weeks prior to admission he complained of an "itchy skin."

Six years before admission, an appendectomy was performed because of pain in the right flank; the appendix was said to have been normal. The patient was told at this time that he suffered with kidney trouble. He had no further urinary symptoms until three years before admission, when, following an attack of left-flank pain, he noted dark-red urine that persisted for several days. After examination of the urine, a physician told the patient that it contained blood. The past history was otherwise irrelevant.

Physical examination revealed a well-developed, deeply jaundiced man, who complained often of itching of the skin. The abdomen was soft, and there was no tenderness. No masses were felt. The liver edge was not palpable. Examination of the heart and lungs was negative.

The blood pressure was 148 systolic, 92 diastolic. The temperature was 98.6°F., the pulse 100, and the respirations 21.

Examination of the blood revealed 70 per cent hemoglobin and a white-cell count of 11,600 with a normal differential count. A blood Hinton reaction was unsatisfactory. The serum bilirubin was 4.75 mg. per 100 cc. direct and 6.75 mg. indirect. The nonprotein nitrogen was 44 mg. per 100 cc. Examination of the urine was negative except for a +++ test for bile, a rare red cell and an occasional white cell. The stool was guaiac negative. The prothrombin was 33 seconds (normal, 18 seconds).

A gastrointestinal series revealed considerable spasm of the antrum of the stomach. The duo-

denum showed no evidence of ulceration or constant pressure defect. A barium enema was negative. A flat film of the gall-bladder area showed no definite evidence of stone.

Operation was performed on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. F. DENNETTE ADAMS: This patient was doubtless operated on for biliary-tract obstruction. The history is somewhat meager, and before proceeding with a discussion of the case, I shall ask Dr. Mallory to inspect the hospital record and see if answers to any of the following questions are available: Was there anorexia, nausea or vomiting shortly after the acute upper respiratory infection subsided? Did the patient receive any form of medication other than the sulfanilamide? Was the spleen palpable? What was the differential count? Was there fever after the respiratory infection subsided? What was the color of the stools?

DR. TRACY B. MALLORY: There seems to have been a very slight degree of anorexia. The spleen was not felt. The polymorphonuclear count ranged from 70 to 90 per cent; there were no abnormal cells. Up to the time of operation, the temperature was normal, and the respirations were constant at 20. The single stool examined was reported to be dark brown.

DR. ADAMS: Would it be fair to ask the roentgenologist some questions before proceeding?

DR. MALLORY: Yes, at any time.

DR. LAURENCE L. ROBBINS: The barium enema was said to be negative. The only films that show the liver and the spleen are these. Neither appears enlarged.

DR. ADAMS: Is there any enlargement of the gall bladder?

DR. ROBBINS: No.

DR. ADAMS: What about the kidneys?

DR. ROBBINS: The left kidney is normal, and I think the right kidney is also normal.

DR. WILLIAM B. BREED: The spasm of the antrum is of no significance?

DR. ROBBINS: Only of suggestive value. We see pylorospasm occasionally in cases of acute cholecystitis.

DR. BREED: Was there pylorospasm in this case?

DR. ROBBINS: That would be determined chiefly on fluoroscopy. However, there is narrowing of the antrum on all the films; this is indicative of some spasm.

DR. ADAMS: The fundamental problem in this case is to decide whether the jaundice was due to intrahepatic disease or to biliary-tract obstruction. With a sixty-six-year-old man with progressive

painless jaundice, one thinks immediately of obstruction due to carcinoma of the pancreas. Yet we have very little evidence on which to establish such a diagnosis. There were no preliminary digestive symptoms, no weakness and no loss of weight, which one often sees early with carcinoma of the pancreas. What is more important, neither the liver nor the gall bladder was shown to be enlarged clinically or roentgenologically, and no pressure defect of the duodenum was observed roentgenologically. Furthermore, the brown color of the stool rules out complete block. The only evidence in favor of obstruction is provided by the van den Bergh test: when, as in this case, the direct value is as high as 70 per cent of the total value, an obstructive type of jaundice is indicated. However, *I always dislike basing a diagnosis on a single laboratory test when the clinical picture is not typical.* I am further confused by the fact that the patient is reported clinically to have been deeply jaundiced, whereas the van den Bergh reaction indicates at most only moderate jaundice.

If the case were one of obstructive jaundice, carcinoma of the head of the pancreas would be most likely. There is certainly nothing to suggest the other common cause of obstruction—stone in the common duct. A remote possibility that deserves brief mention is that the obstruction might have been due to extension of a slowly growing tumor of the right kidney. We have no direct evidence, to be sure, but the two attacks of hematuria cannot be entirely disregarded.

What have we on the other side of the question? This patient was presumably perfectly well until he developed a streptococcal infection of the throat. That the infection was a fairly severe one might be postulated on the basis of the fact that he was given sulfanilamide. Following this illness, he was never entirely well, and four weeks after its onset the jaundice appeared. So-called "catarrhal jaundice" is often preceded by a respiratory infection, but usually appears within a few days—not after four weeks. Despite the interval, however, I cannot convince myself that the jaundice was not related to the infection, and that when the patient entered the hospital he was suffering from intrahepatic disease. Leukocytosis is not seen in simple catarrhal jaundice; yet it is not inconsistent with a severer form of toxic or infectious hepatitis that is proceeding toward acute yellow atrophy. That this stage of yellow atrophy had not been reached, however, is indicated by the absence of fever and other serious systemic signs. Occasionally, one encounters acute cholangitis secondary to severe streptococcal or pneumococcal infection, but this is not likely in this case *because the patient was not sick enough, did not*

have a sufficiently elevated leukocyte count, and had no enlargement or tenderness of the liver. Could the jaundice have been related to the sulfanilamide? I doubt it, for if so, it would have appeared much sooner.

To summarize, there does not appear to be sufficient evidence on which to base a diagnosis, which is often true in cases of jaundice. As I said earlier, at first glance one would be suspicious of obstructive jaundice due most likely to carcinoma of the pancreas. But none of the expected or corroborative signs of biliary obstruction were present, and the illness started with a respiratory infection. Frankly, I am rather surprised that the surgeon was willing to explore so promptly. Had this patient been under my care on the medical service, I am certain—*unless there were other facts available that do not appear in the record*—that I should have pursued a course of watchful waiting for a week or ten days, treating the patient for acute intrahepatic disease and following the clinical course, particularly the progress of the jaundice. In the absence of any improvement, I should have recommended exploration, because of the impossibility of differentiating biliary obstruction and intrahepatic disease.

On the evidence available, my diagnosis is acute hepatitis following an acute upper respiratory infection.

DR. MALLORY: Could we have an opinion from the surgical side? Dr. Sweet, would you be inclined to explore this man?

DR. RICHARD H. SWEET: I do not know. From what I have heard this morning, I should be inclined to agree with Dr. Adams. I should have wanted a little more study, especially about the relation between the evidence of obstruction and the van den Bergh reaction. The fact that there was apparently a dark-brown stool on one occasion seems to be slightly inconsistent. I might have studied that situation a little more.

DR. ADAMS: Will the surgeon who operated on this man tell us why he operated so promptly?

DR. MALLORY: Unfortunately, he is not here.

CLINICAL DIAGNOSES

Adenocarcinoma of ampulla of Vater.
Pancreatitis.

DR. ADAMS'S DIAGNOSIS

Acute hepatitis.

ANATOMICAL DIAGNOSES

Papillary adenocarcinoma of ampulla of Vater.
Obstructive jaundice.

Operative wound: resection of duodenum and portion of head of pancreas, gastrojejunostomy and cholecystoduodenostomy.

Abscess of pancreas, with extension into retro-peritoneal tissues.

Intrahepatic cholangitis.

Arteriosclerosis, moderate: aortic and coronary

PATHOLOGICAL DISCUSSION

DR. MALLORY: The patient was explored, with a preoperative diagnosis of obstructive jaundice. At operation, a small mass could be felt in the duodenum in the region of the ampulla. The head of the pancreas felt normal. The common bile duct was somewhat dilated and contained bile. It was believed that tumor was unquestionably present, either in the head of the pancreas or in the duodenum, and it was decided to do a block dissection. Accordingly, the stomach was divided in the antral region, and the duodenum was cut just before the ligament of Treitz. The common duct was divided, the pancreas was resected about a third of the way back from the head, and the entire block of tissue was removed in one piece. When it was opened, a slightly papillary and very slightly ulcerated tumor was found in the wall of the duodenum surrounding the ampulla of Vater. On microscopic examination, it proved to be a well-differentiated carcinoma, evidently primary in the ampulla. There was one regional node that showed metastases. Following operation, the patient began to run a septic temperature, and from that time on failed rather rapidly, dying in about two weeks.

At autopsy, extensive necrosis was found in the head of the pancreas. A large abscess had burrowed from the pancreas down into the right gutter. There was likewise a cholangitis, and some degree of hepatitis. It would not be possible to say from the autopsy findings whether the cholangitis and hepatitis had been present before operation. At any rate, there was no established biliary cirrhosis, although there was considerable infection in the bile ducts of the liver.

CASE 28332

PRESENTATION OF CASE

A forty-one-year-old Syrian barber was admitted to the hospital because of recurrent attacks of vomiting.

The patient was well until five years before entry, when he suffered an illness lasting about ten days and characterized by nausea and vomiting. The night preceding the illness, the patient had eaten and drunk heavily. There was no fever, jaundice or other symptom. The trouble abated spontaneously, leaving the patient well until a year later, and again the year after that, when he experienced a similar illness, each period lasting ten days. Seven months before entry, the patient

had a fourth attack of nausea and vomiting, this time preceded by a month of anorexia and slight weakness. He visited a community hospital, but returned home after a few days, his trouble having stopped. Anorexia, fatigue and some nausea remained. After a month, the vomiting recurred, following a roentgenologic examination of the gastrointestinal tract. This examination showed a "filling defect at the pylorus." The patient entered another community hospital, where he was given gastric lavage and intravenous feedings. After a week, he stopped vomiting. He was placed on an ulcer diet, and improved readily. In the next five months, he steadily lost weight (about 25 pounds in all) and suffered considerable nausea, with occasional vomiting. At times he had mild diarrhea. Ten days before entry, a final attack of severe vomiting began, persisting until the day he came to the hospital.

About twenty years before entry, the patient had a soft sore on the penis, lasting several weeks. Ten years later he had gonorrhea, with a residual stricture of the urethra that caused him persistent difficulty in starting his stream.

The family history was irrelevant.

On admission, the patient appeared chronically ill, emaciated and dehydrated. The pupils were wide and irregular, and reacted poorly to light and only slightly better to accommodation. The fundi were normal. The heart and lungs were not remarkable. The liver edge was palpable on inspiration, but was smooth and not tender. The urinary bladder rose to two fingerbreadths below the umbilicus. The prostate was twice the normal size and symmetrical, without palpable nodules. The reflexes were equal and active. Vibration sense was present, but position sense was impaired.

The blood pressure was 130 systolic, 85 diastolic. The temperature was 99°F, the pulse 85, and the respirations 20.

Examination of the urine showed a ++ test for albumin, and a sediment with 20 white cells and rare red cells per high power field. The red-cell count was 7,600,000 with 14 gm. hemoglobin, and the white cell count 14,700 with 68 per cent polymorphonuclears, 29 per cent lymphocytes and 3 per cent monocytes. The blood Hinton reaction was positive. The serum protein was 4.8 gm. per 100 cc., with an albumin-globulin ratio of 1:3. The nonprotein nitrogen was 26 mg. per 100 cc., and the van den Bergh reaction was normal; the phosphorus was 2.4 mg. per 100 cc., the phosphatase 31 Bodansky units, and the prothrombin time 25 seconds. Three stools were guaiac negative. Gastric aspiration produced 125 cc. of greenish, guaiac-negative fluid. A lumbar puncture showed clear fluid under normal pressure, with a cell count of 16 lymphocytes, a total protein of 32 mg.

per 100 cc., a + ammonium sulfate ring test, a positive Wassermann reaction and a gold-sol curve of 4332211000.

Roentgenographic examination of the upper gastrointestinal tract showed thickening of the folds of the stomach, with ready opening of the pylorus. The duodenal cap was rather small, and there was some narrowing at the junction of the first and second portions of the duodenum. After barium passed into the duodenum, it extended into an apparently dilated common duct, cystic duct, gall bladder, major hepatic ducts and some minor intrahepatic branch ducts. The first portion of the duodenum then showed irregular filling defects and two or possibly three fine fistulous tracts passing from this part of the duodenum to the gall bladder (Fig. 1). In

FIGURE 1.

This photograph shows barium filling of the gall bladder (upper left) through three small fistulas passing up from the deformed duodenal cap.

re-examination on the following day, the fistulous tracts failed to fill with barium.

The patient was given intravenous fluids, with resultant relief of dehydration and restoration of the red-cell count to normal. He took fluids well, but vomited several times, usually in large quantity. He had no pain until the night of the seventh hospital day, when he began to complain of cramping in the lower abdomen. At this time, the abdomen was soft, with loud peristaltic sounds. The temperature was 101°F. An enema produced good results and relieved symptoms temporarily. The next morning, the patient suddenly collapsed. When seen a few minutes later, he was unconscious and quite cyanotic, with a blood pressure

of 40 systolic, 0 diastolic. The pulse and respirations were but slightly elevated. Examination of the chest was negative. The abdomen was soft and silent, not distended. The patient was given intravenous fluids, and transfusions of both blood and plasma. He responded within half an hour. In the course of the day, he developed increasing distention, and complained intermittently of pain in the left lower quadrant. The temperature returned to normal. The next day, there was generalized abdominal tenderness, centering in the left lower quadrant.

The patient was given constant gastric suction and intravenous fluids. He became unconscious on the evening of the ninth hospital day, and died five hours later.

DIFFERENTIAL DIAGNOSES

DR. RICHARD H. SWEET: A few comments on certain aspects of the history are in order. "Seven months before entry, the patient had a fourth attack of nausea and vomiting, this time preceded by a month of anorexia and slight weakness." This suggests something different, a new train of symptoms.

This examination showed a "filling defect at the pylorus." One wonders if the patient was not beginning to suffer from an obstructing lesion, which produced the anorexia, fatigue and, perhaps, the nausea and the loss of weight and strength.

"The pupils were wide and irregular, and reacted poorly to light and only slightly better to accommodation"; this suggests Argyll-Robertson pupils.

"The urinary bladder rose to two fingerbreadths below the umbilicus." One begins to think seriously about tabes, and the spinal-fluid findings are confirmatory.

"The prostate was twice the normal size." That might have entered into the picture. The patient might have had obstruction of the urethra because of an enlarged prostate.

He had a fairly normal temperature and a reasonably normal differential count. One might assume that he was not suffering from an inflammatory process or an acute infection. If he had a carcinoma of the pylorus, one would expect to see blood in the stools.

"Gastric aspiration produced 125 cc. of greenish, guaiac-negative fluid." Once again, doubt arises regarding the correctness of the first impression that he might be suffering from carcinoma of the stomach.

May we see the x-ray films?

DR. LAURENCE L. ROBBINS: There is quite definite thickening of the folds of the stomach, but as nearly as I can make out, this is antrum and this

represents the duodenal cap. Here, of course, is the common duct filled with barium, and here must be the gall bladder, with the cystic duct visible in this region. These spot films demonstrate the fistulous tracts between the gall bladder and the first portion of the duodenum.

DR. SWEET: Do you think the biliary system filled through the fistulas or by regurgitation through the common duct?

DR. ROBBINS: Not having seen it fluoroscopically, I do not know, but the appearance of the common duct in the distal portion is not what one sees with retrograde filling. I should guess that it had filled through the fistulas.

DR. SWEET: So that we have the problem in this case of deciding what was the cause of the fistulas. In surgical practice, one encounters relatively few causes of that condition. The commonest is ulceration from the gall bladder into the duodenum, with necrosis of a portion of the gall bladder, usually attributed to pressure from a stone in association with infection. Most of the cases of gallstone ileus result from the passage of a large stone directly from the gall bladder through this wall of the duodenum, down into the intestinal tract. This causes a large fistulous opening. Carcinoma of the gall bladder, in my experience, rarely leads to a condition such as this. Here is a fairly normal-looking gall-bladder shadow. There is a well-defined common-duct shadow, and one might exclude carcinoma arising in the region of the cystic duct. Carcinoma of the duodenum is exceedingly rare. The few that I have seen were in the third portion.

Could the fistula have been due to a syphilitic lesion? Are gummas seen in this region? If so, would a gumma produce ulceration through the duodenum and into the gall bladder? I doubt it. The patient was a Syrian. Did he have echinococcal disease? There is no evidence for it, at least no x-ray evidence, and no mention of enlargement of the liver. Echinococcal cysts that obstruct the common duct from the passage of daughter cysts down the duct are occasionally encountered. In this case, however, there was apparently no common-duct obstruction, although one cannot be sure because one does not actually see that the barium went out into the duodenum through the common duct. There was no jaundice. According to the history, I believe I can exclude echinococcal disease. No echinococcus fixation test was done.

Since I cannot answer the question about the relation of syphilis, I shall go on with this lengthy and puzzling story. I do not know why the patient died or what he had. I believe he must have had peritonitis, but how he developed it, I am sure I cannot tell. I should think that, if he had had

leakage from one of the fistulas in the right upper quadrant, the tenderness would have been maximal there or in the right lower quadrant instead of the left.

What conditions give rise to peritonitis in the left lower quadrant? Of course, the organs that one finds there—the sigmoid and so forth—may be the cause. Conditions arising in the upper abdomen may include some retroperitoneal hemorrhage or evacuation of an abscess retroperitoneally from the pancreas. Fluid arising in the upper abdomen from perforation of the stomach, duodenum, gall bladder or common duct usually passes down on the right side. Of course, I cannot tell; I did not see the patient. It may have come down on the right and gone over to the left side, but I get the impression from this—whatever the sudden episode was—that he had something producing the maximum of reaction in the left lower quadrant. It is fair to assume that the patient had as a final episode a generalized peritonitis unless there was something else, like intra-abdominal hemorrhage, which one could not tell anything about from this record. The case is exceedingly puzzling. To summarize, I believe the patient had some peculiar lesion in the duodenum or gall bladder, which I suppose was the origin of the sudden abdominal catastrophe that was the cause of death.

DR. TRACY B. MALLORY: Are there any questions or suggestions?

DR. FULLER ALBRIGHT: How about a ruptured aneurysm?

DR. MALLORY: Where?

DR. ALBRIGHT: I do not know.

DR. SWEET: That is what I meant when I said "intra-abdominal hemorrhage."

DR. MALLORY: Dr. Dieuaide, how much of a role would you consider syphilis to have played in this process?

DR. FRANCIS R. DIEUAIDE: I think it probably played none. Gummas may occur in that region perfectly well, but are unusual. I do not believe, however, that a syphilitic process in this region would be likely to be associated with fistulas. The fistulous nature of the lesion is an important clue. A gummatous process here would be an adhesive, more or less solid, mass. Accordingly, I should abandon syphilis as the explanation of the lesion, although the patient certainly had central-nervous-system syphilis. I should consider it meningovascular rather than tabetic. I do not believe an aneurysm could be used to explain the whole story, although a ruptured aneurysm could be the explanation of the terminal episode.

DR. ALBRIGHT: I believe the fistula was due to stone.

nurses-aide committee, a Red Cross nursing consultant may visit the hospital, or information may be obtained from the state nursing council or the state nurse-examining board.

Each nurses' aide agrees to give one hundred and fifty hours of service in each calendar year, preferably within a three-month period. In case of need for war service, nurses' aides must be prepared to serve locally in the emergency for as long as they are needed.

The Office of Civilian Defense has asked its regional-office representatives to work out plans for stimulating the recruitment of nurses' aides to provide the needed strength to meet war demands. These plans are to be put into effect through the officially constituted authorities, including state and local chiefs of emergency medical service, their nurse deputies, local Red Cross chapters and local civilian-defense volunteer offices.

Without the assistance of large numbers of nurses' aides to supplement the registered nurses, many hospitals report that they would be unable to provide adequate nursing services. If coastal and industrial cities are subjected to enemy attack, the need for nurses' aides will be greatly accentuated. The goal of 100,000 trained nurses' aides must be reached, the Medical Division declares. In no other branch of service can women be of greater value to the war effort.

CORRESPONDENCE

MEDICAL ADVISORY COMMITTEE FOR INDUSTRIAL ACCIDENT BOARD

To the Editor: When the Massachusetts Workmen's Compensation Act became a law, a committee representing the medical profession met and discussed the important medical aspects of such an act; at the meeting, this committee established a few fundamental policies which were adopted by the Industrial Accident Board and became the backbone of the compensation law. These policies have developed and grown as a result of the continued advice and study by representatives of the medical profession as a whole.

I believe that the success of the Industrial Accident Board in Massachusetts, and its high standing in other states, is due in a considerable degree to the assistance we have received from many members of the medical profession recognized as specialists in their respective lines of work.

It is the desire of the Board to continue this policy and, although many are well qualified throughout the Commonwealth to serve the Board in an advisory capacity, it is expedient and desirable that such a committee be located near the offices of the Board.

I am, therefore, pleased to announce the appointment of the Medical Advisory Committee as follows:

Dr. Cadis Phipps, chairman, 587 Beacon Street, Boston. Director, First and Third Medical Services, and physician-in-chief, Third Medical Service, Boston City Hospital; professor of medicine and head of Department of Medicine, Tufts College Medical School; diplomate, American Board of Medicine.

Dr. William E. Browne, secretary, 587 Beacon Street, Boston. Associate, Surgical Staff, Beth Israel Hospital; surgeon-in-chief, Second Surgical Service, Carney Hospital; clinical professor of surgery, Tufts College Medical School; fellow, American College of Surgeons; diplomate, American Board of Surgery.

Dr. Donald Munro, Boston City Hospital, Boston. Surgeon-in-chief for neurological surgery, Boston City

Hospital; associate professor of neurological surgery, Boston University School of Medicine; assistant professor of neurological surgery, Harvard Medical School; member, American Neurological Association, New England Surgical Society and Society of Neurological Surgery; fellow, American College of Surgeons; diplomate, American Board of Neurological Surgery and American Board of Surgery.

Dr. William A. Rogers, 266 Beacon Street, Boston. Instructor in orthopedic surgery, Harvard Medical School; member, American Orthopedic Association; fellow, American College of Surgeons; diplomate, American Board of Orthopaedic Surgery.

Dr. John G. Downing, 520 Commonwealth Avenue, Boston. Assistant dermatologist, Boston City Hospital; assistant professor of dermatology, Tufts College Medical School; consultant, United States Public Health Service; member, Boston Health Department, American Academy of Dermatology and Syphilology (vice-president), American Association of Industrial Physicians and Surgeons, American Dermatological Association, Society of Investigative Dermatology and New England Dermatological Society; diplomate, American Board of Dermatology and Syphilology.

Dr. Ariel W. George, 43 Bay State Road, Boston. Member, American Roentgen Ray Society, British Institute of Radiology, New England Roentgen Ray Society and Radiology Society of North America; diplomate, American Board of Radiology.

Dr. Timothy Leary, 43 Bay State Road, Boston. Medical examiner, Suffolk County; professor of pathology, emeritus, Tufts College Medical School; lecturer in legal medicine, Harvard Medical School.

These men are recognized as specialists by members of their profession and, I believe, will render invaluable service to the Commonwealth.

EMMA S. TOUSANT, *Chairman*
Industrial Accident Board

DEATH RATE IN INFANCY AND CHILDHOOD

To the Editor: The editorial that appeared in the July 9 issue of the *Journal* on the subject, "Death Rate in Infancy and Childhood," has been the subject of discussion among the members of our division staff.

We have read the article by Dublin and Spiegelman therein quoted. The three years chosen for the study include the very last of the years (1937) when the Massachusetts' infant mortality rate was above 40. In the remaining two years, 1938 and 1939, the rate was below 40, and it has continued to decrease. The rates for these years are as follows: 1937, 43.8; 1938, 39.1; 1939, 37.4; 1940, 37.5; and 1941, 35.3.

We fully appreciate the problems presented by the unusual conditions of the present and the future and shall do our utmost to "hold fast to the ground that has already been gained." To that end we feel sure we may call on the continued co-operation of the medical profession in Massachusetts.

Boston

WILLIAM HENRY WELCH

To the Editor The excellent editorial on William Henry Welch in the July 23 issue of the *Journal* reminds me of the esteem shown him by his associates. I recall walking the hospital wards with Dr Osler in the early days of Hopkins. Discussing a medical problem, Dr Osler inquired, 'Well, what does the king of all pathologists say to this?'

A present-day visitor to the school is struck by the inscription across the façade of the Anatomical Building, 'The Woman's Fund Memorial Building 1894'. This marks an end to the long struggle to raise sufficient money to warrant opening the school. A group of women with the timely help of Miss Mary Garrett, offered the University a fund of half a million dollars on the conditions that women should be admitted on the same terms as men and that the entrance requirements should be on a university level.

Some years later, Dr Welch, speaking at the annual meeting of the Association of American Universities on 'Women in Medicine,' said 'The faculty of Hopkins deserves little credit for the success of the school. Only Osler, Kelly and Hurd signed a letter of acceptance to the proposition of the women, the rest of us were frankly skeptical about the experiment of coeducation. Now, after the actual experience, I am sure that I report my colleagues correctly that we would unanimously vote to continue coeducation in the medical school. That medical education belongs to a university and that women are to participate in the intellectual aspect of medicine mark an epoch in American medicine.'

Among the treasures also to be seen by the visitor, is the Sargent group of the Great Four. Of Dr Welch sitting in front, Dr Osler once remarked, 'One sees his strength as an aura.'

REPORT OF MEETING

HARVARD MEDICAL SOCIETY

A regular meeting of the Harvard Medical Society was held at the Peter Bent Brigham Hospital on April 14, with Dr C. Sidney Burwell presiding. There was a case presentation by the medical service.

A sixty-four year old man was first admitted in 1940 because of asthmatic breathing of eighteen months' duration. Physical examination was essentially negative except for the liver, which could be palpated 4 cm. below the right costal margin. There were no significantly enlarged lymph nodes, and the spleen was apparently normal. The red-cell count was 4,800,000, and the white cell count 11,000 with a normal blood smear. In December 1941, the patient returned because of a loss of 15 pounds in weight, weakness and gaseous eructations. Physical examination revealed an enlarged liver and a palpable mass in the left upper quadrant. This finding was confirmed by x-ray studies as the spleen, no gastrointestinal defects were demonstrable. On admission to the medical service two weeks later, the patient was found to have a considerable amount of fluid in the left pleural cavity and generalized lymphadenopathy, as well as hepatomegaly and splenomegaly. The white cell count was 126,000 with 93 per cent large lymphocytic cells. One thousand cubic centimeters of fluid was removed from the left pleural cavity. After three spray treatments of x-rays of

50 r each, directed from the clun to the knees, there was within twelve days a decrease in the white-cell count to 13,000. The percentage of lymphocytes remained about the same. Two months later, there was great subjective improvement, and the leukocyte count was 5000, three months later, the white cell count was 7000, with 50 per cent polymorphonuclear neutrophils.

In the discussion, Dr William Dameshek questioned whether regional roentgen ray therapy is not better for decreasing the white cell count and increasing the red cell count. Dr M. C. Sosman stated that much better results are obtained with spray therapy using small dosage. There is apparently less systemic reaction, and the erythrocyte count rises more gradually and is longer sustained. Regional roentgen ray therapy is now used by him only for the alleviation of subjective local signs.

The speaker of the evening was Dr Louis Hamman of Johns Hopkins University School of Medicine, who discussed 'The Diagnosis of Leukemia.' This disease is now better known for its bizarre onset in many cases than was formerly noted. A patient may present anything from a peridental abscess or tachycardia to change of bowel or urinary habits. Any of the bodily systems may supply the initial symptom. There is one group in which the early blood picture fails to reflect the true state of affairs, and these conditions are therefore particularly difficult to detect. Another recent development that complicates the diagnosis of leukemia is the recognition of so-called leukemoid reactions which result in almost identical hemograms. These may be the result of irritation or stimulation of the bone marrow, such as that in osteomyelitis and other infections complicated fractures, metastatic cancer completely replacing the active marrow and leading to the establishment of other foci of hematopoiesis, Hodgkin's disease and benzol poisoning which may eventually be exactly the same and has been suggested by some as an etiologic factor. A marrow response to regeneration, as in the acute familial hemolytic jaundice, severe hemorrhage, agranulocytosis and severe infections, and myelophthisis, a condition in which ectopic foci of hematopoiesis arise in the primitive blood forming organs when the marrow is inadequate because of such conditions as osteosclerosis and fibrosis, extensive tumors and the late stages of increased demands on the regenerative system. In the first group the leukocyte count may be very high and there is usually marked eosinophilia and immaturity of the leukocytes. In the second group, there is only moderate leukocytosis and immaturity and less eosinophilia. In the last group the leukocyte count may be anything, but there is often increased immaturity of cells, whereas eosinophilia is not common.

In the diagnosis of leukemia one should be careful not to include any of the above conditions, especially those with a favorable prognosis for there is nothing worse than to have a family prepared for an inevitable death that fails to materialize. When leukocytosis and immature white cells are present the diagnosis of leukemia is not difficult. But this cannot be said of the subleukemic, leukemic and leukopenic stages. In true leukemia, there are always—except perhaps during remissions—some degree of anemia, which may be pronounced too severe with an increase of normoblasts. The platelets are invariably very low. Immaturity of leukocytes occurs in about 90 per cent of the cases, and the cells are often atypical. Various cell families may sometimes be differentiated only by mobility tests.

Dr Hamman cited some case histories to indicate the

problems involved. In one, a seventy-five-year-old man had pericarditis with effusion and no demonstrable blood change for several months. Therefore, a patient may have leukemia for some time without blood changes, and certain diseases may terminally become leukemia. Another case of the same type had symptoms without recognizable changes of the hemogram for four months: a middle-aged woman had recurring fever, with two positive agglutination tests for *Brucella mellitensis*, and tubercle bacilli were cultured from a lymph node before the blood picture became that of leukemia. At autopsy, all organs revealed typical findings of leukemia, but of the more acute type. However, a review of blood smears revealed that there was an early anemia and granulopenia and that the 90 per cent of the "lymphocytes" were in reality myelocytes and myeloblasts. Subsequent smears showed an accentuation of all features of a true leukemia. Clinically, it was concluded that the patient had had this disease from the beginning, with intercurrent Malta fever and localized tuberculosis, but the pathologist stated that the course could not have been of seven months' duration. This raises the question whether leukemia may result from stimulation by poisons, infections and so forth. Malta fever is known to occasion leukemoid reactions.

Another case was that of a fifty-nine-year-old man who was suspected of having a duodenal ulcer but had roentgenologic evidence of it for only a short while. On developing signs and symptoms of a perforation, the patient was subjected to an operation, but no ulcer was found. During and after the convalescence, the pain continued and became severer until it was almost unbearable. Roentgenograms revealed what appeared to be multiple bone metastases, and some slight relief resulted from irradiation therapy. On admission, the blood picture was normal, but the erythrocyte count soon fell, whereas that of the leukocytes rose and more immaturity of these cells became apparent in blood smears. Autopsy a few weeks later revealed characteristic leukemia, the cause of sudden death being a subarachnoid hemorrhage—not a rare occurrence.

In conclusion, Dr. Hamman stated that leukemia may be present for some time with signs and symptoms but no characteristic blood changes, just as well as the opposite. In children, it is likely to simulate acute infections, whereas in adults chronic infection and cancer are usually suspected.

The discussion was opened by Dr. E. A. Stead, Jr., who emphasized the fact that myelocytes are frequently called lymphocytes in unknown smears. Dr. Chester S. Keefer asked whether leukemia might not be caused by multiple small doses of irradiation. Dr. Louis K. Diamond pointed out the difficulties in children, in whom infection so often elicits a bizarre blood response. More than 50 per cent of his leukemic patients were in the leukopenic stage on admission, and biopsy is, therefore, often used. Signs and symptoms of rheumatic fever are fairly common and are always associated at the onset with relatively low leukocyte counts. The importance of thrombocytopenia as a diagnostic aid was emphasized.

In answer to a question by Dr. Sosman on how best to treat early cases when the total white-cell count is essentially normal, but the percentage of young forms is high, Dr. Hamman stated that irradiation therapy may actually be harmful and should be reserved for the onset of symptoms. Temporarily, supportive treatment should be employed.

BOOK REVIEW

Behind the Mask of Medicine. By Miles Atkinson, M.R.C.S., L.R.C.P. 8°, cloth, 348 pp. New York: Charles Scribner's Sons, 1941. \$3.00.

This book, like those of "The Doctor Looks at —" sort, is designed for lay consumption. It contains some history and considerable philosophising concerning the relation of the patient to the doctor, medical economics and the present and potential status of medical practice.

Dr. Atkinson is fluent, sometimes thought provoking, and not infrequently amusing. But the title of the book, connoting as it must in some minds something camouflaged or deliberately concealed, is inappropriate and unfortunate. Moreover, the author is sometimes just a little too glib, a shade too cocksure. His insouciance is the more conspicuous in the face of certain careless errors and misleading implications. It is not true, for example, that vitamin E is "the latest of the vitamin discoveries." It is not true that a blood count is "the only laboratory procedure which is absolute." The statement that "some small boys keep for preference their testicles high up out of the way where they do not develop properly" will not have much meaning for most readers. Furthermore, Christopher Wren is hardly to be bracketed with Francis Bacon and Sir Isaac Newton as a motivating force in seventeenth-century science.

This is not meant for captious criticism; it is simply that carelessness about minutiae tends, even with some injustice, perhaps, to break down an author's credit with those in the know. Dr. Atkinson has some chapters that are quite free from either factual blemishes or "wisecracks"; the chapter on the plight of the hospitals deserves every doctor's, every hospital director's and every trustee's reading. That the chapters on socialized medicine and the future will provoke controversy is inevitable,—those are controversial subjects,—but nothing against the author.

All in all, it is a book to be read with a certain added salinity of the reader's seasoning—a good dose of salt, in spots. If one knows how to add it, well and good; if he has any doubts how, it would be wiser to let it alone.

SURGICAL TREATMENT OF SEVERE ORCHITIS IN MUMPS*

CONRAD WESSELHOEFT, MD,† AND SAMUEL N. VOSE, MD‡

BOSTON

THE early surgical treatment of severe orchitis of mumps accomplishes prompt relief of pain and saves the testicle from subsequent atrophy. The operation must be done before the testicular tissue has undergone pressure necrosis, but should be reserved for cases in which the severity of the symptoms warrants such interference.

In 1864, Henry Smith¹ advised multiple punctures of the tunica albuginea for orchitis; he stated that this operation had been in vogue in Paris for at least two years. One finds references to this work in the literature on mumps, but the orchitis so treated was of gonorrheal origin. Comby,² in his book on mumps published in 1893, makes no mention of any surgical treatment of orchitis. Schottmüller,³ in 1904, advised incision through the tunica vaginalis for release of the hydrocele fluid in mumps orchitis. In 1912, G. G. Smith⁴ treated 2 patients with mumps orchitis by incising the tunica albuginea, and in 1920, Billenger and Elder⁵ reported on 3 patients so treated.

Edema is characteristic of the pathology of an invasion of gland tissue by the mumps virus. The dense fibrous layer covering the testicle offers resistance to this swelling. If the edema develops rapidly, the internal pressure causes intense pain, often associated with backache. Repeated chills, with high fever, nausea, vomiting and even delirium, may take place. The pain may be so excruciating that $\frac{1}{2}$ gr of morphine fails to give relief, and so tender is the part that the patient objects to the most gentle examination. This situation may develop rapidly in fulminating cases, in which the testicle swells rapidly and hydrocele fluid forms. The scrotum becomes

markedly edematous and bluish red. In other cases, the testicle may gradually reach double its normal size in forty-eight hours, with only moderate discomfort, slight tenderness, no edema of the scrotum and only a moderate fever. It may subside gradually, when no surgical interference is necessary, or it may suddenly develop into the fulminating picture described above.

Although mumps is manifested by a parotitis in the vast majority of cases, it is well to keep in mind that the parotids may show no swelling, and that the submaxillary and sublingual glands may take the brunt of the attack. Furthermore, the involvement of the salivary glands may follow other manifestations of the disease. Thus, an orchitis, a pancreatitis or an encephalitis may precede, accompany or follow the parotitis. Finally, the only manifestation of mumps may be in one of these organs remote from the salivary glands. Here, the diagnosis is based on the circumstantial evidence of exposure, the incubation period of approximately eighteen days and the course pursued. In 1920, Wesselhoeft⁶ collected from the literature 30 cases of primary orchitis and 64 cases in which orchitis occurred without involvement of the salivary glands. Since then, several more have been reported. During epidemics, such cases crop out, and to add to the difficulty, they may occur in patients who have had mumps previously. However, one attack of the disease, even though it affects only one salivary gland, usually conveys a lasting immunity.^{7,8}

Orchitis very rarely occurs before the age of puberty, but such cases have been recorded. At and above that age, its incidence in mumps is 18 per cent. Collected reports from the literature indicate that under epidemic conditions both testicles are likely to be involved in 1 out of 6 cases.⁹

In the follow-up examinations of 347 cases atrophy was revealed in 190, or 54.7 per cent.⁶ Sterility as a result of atrophy is actually rare.⁷ In

*Presented at a meeting of the New England Section, American Urologic Association, Boston, April 23, 1942.

†From the Haynes Memorial Massachusetts Memorial Hospitals.

‡Clinical professor of communicable diseases, Harvard Medical School; associate professor of theory and practice, Boston University School of Medicine; physician in chief, Haynes Memorial Massachusetts Memorial Hospitals.

§Associate professor of genitourinary surgery, Boston University School of Medicine; surgeon in chief, Genitourinary Department, Massachusetts Memorial Hospitals.

the unilateral cases, the unaffected testicle serves adequately for procreation. In the bilateral cases, enough undamaged tubules remain to supply spermatozoa, but probably not in the usual abundance, and thus reduce the chances of conception to an indeterminable degree. Sterility is not to be confused with impotence. As pointed out by Stengel,⁹ sterility implies the lack of sufficient sex cells, whereas impotence refers to the inability to complete the sexual act. Fear of sterility after mumps orchitis sometimes leads to a mental complex that may promote impotence.

A description by Wolbach of the pathology of mumps orchitis is incorporated in the paper by G. G. Smith.⁴ In the biopsy specimen, it was found that the process did not affect the testicular tissue uniformly. Some groups of seminiferous tubules were completely destroyed. The interlobular connective tissue throughout was edematous, and between the tubules there were fibrin, small areas of hemorrhage, and many polymorphonuclear and endothelial leukocytes. Manca¹⁰ subsequently confirmed these findings in an autopsy specimen. The pathology of the parotitis in the experimental disease in monkeys has been described by Johnson and Goodpasture,¹¹ who found edematous swelling of the gland with pin-point hemorrhages and destructive changes through the parenchyma, including disintegration of the acinar cells and the presence of cytoplasmic inclusions. There was an infiltration of mononuclear phagocytes, and later of lymphocytes, into the necrotic areas and about the ducts. The authors found that healing took place through removal of the debris and regeneration of acinar epithelium, which restored the gland without scarring. In these two descriptions, there is a contrast that is of importance to the prognosis. Wolbach described a well-advanced orchitis in which the inflammation had called forth polymorphonuclear cells. In severe orchitis, the blood counts tend to shift from a lymphocytosis to a polymorphonuclear leukocytosis. This shift in the blood picture is comparatively rare in parotitis, involvement of the submaxillary glands, pancreatitis, encephalitis and oöphoritis. The reason for this rise in neutrophils seems to be a true pressure necrosis in the testicle, in addition to the benign and reparable inflammatory process seen in other organs. Furthermore, in no other gland does mumps invasion result in atrophy, with the possible exception of the prostate.¹²

The pathology in a totally atrophied testicle has been described by Stolz.¹³ The resistance of the tunica albuginea appears to be responsible for the severe pain and the pressure necrosis that leads to subsequent testicular atrophy.

The virus of mumps may invade the seminiferous tubules of the testicle, the epididymis and the vas deferens in varying degrees of severity, either simultaneously or separately. Moreover, in rare cases, the prostate and the seminal vesicles may also be involved.

Schottmüller³ recommended incision through the wall of the scrotum for the purpose of releasing the hydrocele fluid. This operation, however, did not relieve the pressure necrosis going on within the testicle, and therefore accomplished little or nothing. In our experience, hydrocele fluid increases more rapidly from an epididymitis than from an orchitis. However, if either of these conditions exists in a severe form, the other organ also becomes involved to a certain degree. The epididymitis, which is relatively less painful than that caused by gonococcal infection, is as self-limited as the swelling of the parotid. As the inflammation in the epididymis diminishes, the hydrocele recedes spontaneously. The only possible value, then, of an incision through the scrotum is to expose the testicle and thus to determine the situation more accurately, especially when the diagnosis is in doubt. In primary cases, the question of differentiation from an early torsion of the testicle may arise; therefore, a view of the testicle may be desirable.

At the onset of orchitis, the scrotal wall is thin, so that one can easily palpate the testicle and any enlargement of the epididymis. If the testicle does not yield to pressure, presents a stonelike hardness and is very tender, it is wise to operate without further delay. As the condition progresses into the severe stage, the actual size and firmness of the testicle become more obscured by the edema of the scrotum and the accumulation of hydrocele fluid.

An incision through the scrotum, which in these cases may be 1 cm. thick from edema, causes a spurt of yellow hydrocele fluid. This spurt may rise like a fountain toward the face of the operator, particularly if a small nick is made in the tunica vaginalis. The incision is enlarged with scissors to about 3 cm., thus exposing the surface of the testicle to view. There is no necessity of delivering the testicle as done by Smith⁴ and Ballenger and Elder.⁵ It may be turned within the scrotum to demonstrate the condition of the epididymis. In severe cases, the tunica presents a surface that does not yield to pressure and may be studded with small petechiae. The tunica albuginea is incised longitudinally to a length of 1.5 cm. The internal pressure may cause the testicular tissue to protrude through the incision. The greater the tension, the less the bleeding. Care is taken to avoid any outwardly visible blood vessel, and

small spurs may be secured by fine ligatures. Another incision, crosswise to the first but beside it, may be made to relieve tension in both directions. The scrotal incision is then stitched with silk, a small rubber-tissue drain or simply an open end of the wound being left to afford an exit for the profuse drainage that follows. The dressing should be secured by a T bandage, with two lines coming up over the groins. This dressing should be changed within two hours, and at frequent intervals through the first twenty-four or forty-eight hours, or as indicated by the amount of drainage.

Nitrous oxide and oxygen is the anesthetic of choice. We attempted to use local anesthesia in one case but without success, because the operation was much too painful. This was the only patient who expressed dissatisfaction with the operation at the follow-up examination. In another

On the follow-up examinations six months and one year later, this case showed some atrophy to have taken place, the testicle being noticeably smaller than the unaffected one; the scar was barely visible in the folds of the scrotum. G. G. Smith⁴ did not report on the follow-up of his 2 cases. Ballenger and Elder⁵ incised the tunica albuginea in 3 cases, and on the follow-up examinations twenty months to three years later, there was no evidence of atrophy.

Twelve patients with severe mumps orchitis were operated on at the Haynes Memorial Hospital (Table 1). Nine of these were followed up six months and one year later. In only 1 of the 9, the patient described above as being operated on late, was there any observable atrophy of the testicle when compared with the unaffected one. In a case followed at a boarding-school infirmary,

TABLE 1. Summary of Results of Treatment of Mumps Orchitis.

TYPE OF CASE	TOTAL NO OF CASES	TESTICLES INVOLVED	NO OF CASES FOLLOWED	TESTICLES WITH ATROPHY	TESTICLES WITHOUT ATROPHY
Severe (operation) . . .	13	14	10	1*	10
Mild (no operation) . . .	14	17	10	0	13
Totals . . .	27	31	20	1	23

*Late operation

case, we used intravenous Pentothal Sodium, but this patient had a temperature of 103°F. at the time and squirmed about during the operation, although entirely unconscious. Furthermore, he remained in a deep sleep for two hours. With nitrous oxide and oxygen, the patient comes out of the anesthetic immediately after the operation. It is surprising how promptly the tenderness of the testicle subsides. While the first dressing is being changed, the incised testicle may be gently palpated without causing undue pain, whereas prior to the operation even the gentlest possible handling is barely tolerated.

There is an immediate feeling of relief after the operation. The temperature drops sharply. One of our patients with a temperature of 105°F. and a mild delirium at the time of the operation was mentally clear half an hour later. The temperature fell to 100°F. in four hours, and an uneventful recovery followed.

The stitches in the scrotum should be left in for one week, since there is a tendency for the wound to gape if they are removed earlier. When the operation is done within forty-eight hours of the onset, the swollen testicle may go down to almost normal size within a week, but more frequently this takes ten days to two weeks. One patient who was operated on late but had high fever still had an enlarged testicle after a month.

the second testicle became involved after the operation on the first; no atrophy took place. Thus, ten testicles were operated on early, with no subsequent atrophy, and one was operated on late, with subsequent partial atrophy.

With the exception of 1 patient operated on in 1929, all occurred in the years 1936-1941 inclusive. During this period, there were 10 cases of mild mumps orchitis at the Haynes Memorial Hospital. Four other mild cases were followed outside the hospital. These patients were not operated on. Follow-up examinations in 10 of these 14 cases revealed no atrophy. The absence of any evidence of atrophy after these mild cases is not in accord with an assertion by Stolz,¹³ based on reports of other observers, that the intensity of the inflammation during the orchitis is not a reliable indication of the amount of atrophy likely to ensue.

We have stressed the rapid fall in the temperature following operation. This statement needs qualification because the involvement of another organ may retard the fall in the temperature or subsequently cause a sharp rise. In 1 case, the second testicle became severely involved and was operated on two days after the first operation. Both testicles were normal in size at the follow-up examination. In 2 severe cases that came to operation, there was an accompanying encephalitis. In 2 of the mild cases

without operation, an encephalitis was the predominant complication. In 1 of these, the temperature rose abruptly to 107°F., accompanied by delirium, when the orchitis was superimposed on the encephalitis, but the testicle was never seriously threatened, and the temperature fell rapidly throughout the night. Aside from a lumbar puncture, there was no surgical interference, and no atrophy of the testicle followed. In 1 case, there was well-marked tenderness over the region of the pancreas, and the temperature was elevated.

The value of heat, cold and other applications, as well as morphine, is, in our opinion, beside the point in severe orchitis, as is any acute condition in which surgery is indicated. The use of convalescent serum is as illogical as it is ineffective. Whether the use of this serum in a case of mumps will prevent orchitis is a debatable question,¹⁴ and outside the scope of this paper. However, there is no doubt that convalescent serum is a valuable preventive against mumps when used soon after exposure.¹⁴

SUMMARY

The rationale of incising the tunica albuginea in severe orchitis is somewhat comparable to that of paracentesis of a bulging, painful drumhead in otitis media. The operation must be done sufficiently early to avoid pressure necrosis in the testicle. It is useless to operate when the process is already on the wane. Early operation relieves pain, reduces the fever and avoids atrophy. It is not indicated in mild cases or those in which an epididymitis predominates. An enlarged, hard, tender testicle, with chills and fever, constitutes the indication for surgical interference. Nitrous oxide and

oxygen is the anesthetic of choice. A rise in temperature after operation signifies an invasion of the virus in some other organ.

The end results of 9 hospital cases and 1 operated on elsewhere are presented. Moderate atrophy took place in the case operated on too late. In the others, there was immediate relief, and no atrophy was apparent at follow-up examinations. Fourteen cases of mild orchitis were observed during this period. The patients were not operated on. A follow-up examination on 10 of these revealed no atrophy. The expected incidence of atrophy after mumps orchitis without surgical interference is 54.7 per cent. Our experience suggests that atrophy occurs only after severe cases, and that by an early operation in such cases atrophy can be avoided.

ECLAMPSIA

KENNETH W. SEWALL, M.D.*

BOSTON

THE purpose of this paper is to review some aspects of eclampsia and to present additional statistics.

ETIOLOGY

The cause of eclampsia remains unknown, in spite of many theories.

Placental infarcts have frequently been discussed as a cause of eclampsia. Recently, Hunt and his associates¹ suggested that placental infarcts and degenerating placental tissue liberate autolysates, which, if massive or if renal function is poor, produce severe late toxemia or eclampsia. Patterson et al.² caused acute placental infarctions, convulsions and death at term in rabbits by total thyroidectomy at the end of the first trimester of pregnancy. They believe that hypercholesterolemia of the fetus resulted in arterial disease, which accompanied fetal hypometabolism, and that placental infarctions and convulsions were due to split-protein products from the infarcted placenta.

Bartholomew and Kracke³ studied a thousand placentas and found acute infarcts in all those from patients who had pre-eclampsia or eclampsia. In their opinion, the infarcts are due to cholesterol-induced arterial disease and the eclampsia to the absorption of split-protein products from the infarcted area. They produced convulsions and death in guinea pigs by the injection of placental decomposition products.

Peters et al.⁴ found that 41, or 13 per cent, in a series of 320 patients with toxemia had had pyelitis or pyelonephritis, which, according to these authors, led to toxemia by producing renal damage and diminishing renal function. However, Mussey and Lovelady,⁵ in a series of 163 patients with pre-eclamptic toxemia or eclampsia, found 6 or 7 who showed symptoms of pyelitis in the puerperium. None gave a history of pyelitis before the first pregnancy, and among 117 cases of pyelitis of pregnancy, 3 patients developed acute hypertensive eclampsia and 1 died of an inflammatory kidney lesion. Prather and Sewall,⁶ studying 72 patients with pyelonephritis during pregnancy who returned to the hospital with a subsequent pregnancy, found that 13 per cent had toxemia. They point out that 10 per cent of all pregnant women have toxemia.

Strauss⁷ observes that 80 per cent of the women said to have toxemia actually have chronic vascular or renal disease before and after the gravid state, and that another 5 per cent have such disease in

acute form. The remaining 15-per cent have toxemia and, under proper care, will have normal succeeding pregnancies; he calls this group the "water-retention toxemias." Such toxemia may be caused primarily by low plasma proteins, excessive sodium intake or, in many cases, both. Anemia, primary renal failure and a rise in intercapillary pressure, as with congestive heart failure or venous obstruction, are conducive to water retention.

Smith and Smith⁸ show that the urinary excretion of estrogenic compounds from the fifth month of pregnancy to term in pre-eclampsia and eclampsia is considerably less than it is in normal pregnancy. In their cases, the level of serum estrogenic substance also failed to show the rise characteristic of normal pregnant women. Venning⁹ and Weil¹⁰ state that the excretion of pregnanediol in normal pregnancy gradually increases until term, but in toxemia there is a sharp decrease. Smith, Smith and Pincus¹¹ show that the ratio of estriol to estrone is about 15:1 in the last month of normal pregnancy, but in pre-eclampsia and eclampsia, this ratio is considerably lower. Pincus and Zahl¹² indicate that the corpus-luteum hormone, progesterone, facilitates the conversion of estrone into estriol, and that the excretion of sodium pregnanediol glucuronide reflects the action of progesterone. The urinary chorionic gonadotropic hormone in normal pregnancy has a peak of excretion in the early months (the twentieth to the fiftieth day after the missed menstrual period, according to Evans et al.,¹³ and at about two months according to Smith and Smith⁸); after this peak is reached, the excretion decreases rapidly and remains constant until term.

Smith and Smith^{14, 15} have shown that the placentas from pre-eclamptic and eclamptic patients contain an abnormally high concentration of prolactin, and that the estrogenic content of these placentas is low; furthermore, the serum prolactin is usually high in pre-eclampsia and eclampsia. They found that low or decreasing pregnanediol and estriol, a high or increasing percentage of estrogenic activity accountable to estradiol, decreasing or absent estrone, and high or increasing ratios of estrogenic potency after hydrogenation characterized the urines of every toxemic case. They believe that toxemia of pregnancy is closely associated with a progressive deficiency of progesterin, a concomitant decrease of estrogen and a

*Instructor in obstetrics, Boston University School of Medicine, second assistant obstetrician, Massachusetts Memorial Hospital.

consequent changed metabolism of estrogen involving greater and more rapid destruction.

Weiss et al.,¹⁶ in a study of a series of autopsies on women who died of eclampsia, noted rapid improvement after the uterus was emptied. In 16 cases in the series, death of the fetus in utero did not result in improvement of the patient. After fetal death, hormones originating in the placenta continued to be eliminated in the urine. The authors believe, since there is no valid evidence that pressure on the ureter or renal artery, primary kidney disease, infection or nutritional disease is primarily responsible for the syndrome, that the presence of a functioning placenta maintains the syndrome and that removal of the placenta is responsible for the improvement. No identifiable chemical substance was found to be responsible. Extracts of placentas from normal or toxemic pregnant women failed to yield pressor substances. Weiss and his associates do not believe that the syndrome occurs spontaneously or has been induced in animals. Their experiments in nonpregnant and pregnant rabbits and rats with Pitressin, estrogenic substances, progesterone, pregnancy-urine prolan, desoxycorticosterone and placental extracts failed to produce the syndrome. They consider the changes observed in the kidneys and other organs during the course of the syndrome secondary to the suspected chemical or "hormonal" changes, but in severe cases this secondary damage to the kidneys and liver can play a role in the vicious circle leading ultimately to convulsions, acidosis and circulatory collapse. They believe that the primary factor initiating the syndrome originates from the placenta; it may be a normal hormonal constituent of pregnancy in abnormal amounts, or in normal amounts acting on a vascular system with a congenital or acquired hyperirritability.

It seems, from the theories discussed, that whatever its cause, eclampsia affects first, or even arises from, the placenta. The chief pathologic damage is to the vascular system. And, possibly, it may have a hormonal origin.

PHYSIOLOGIC PATHOLOGY

A major abnormality during pregnancy is sudden increase in weight due to edema. Water retention can be caused by changes in sodium balance brought about by a high salt intake, or by a large amount of sodium bicarbonate taken for "heart burn."⁷ Anemia, for an unknown reason, is also conducive to water retention. Hormone balance plays a part in water retention, and vitamin lack, diabetes and anything else that disturbs the blood supply to the placenta may cause hormonal

imbalance. Decrease in plasma protein is another important factor in water retention; the albumin fraction is four times as active osmotically as the globulin fraction, so that it is essential to do separate analyses. Hydremia, rise in intracapillary pressure, hypothyroidism, primary renal failure and cardiac failure are other factors. Weiss et al.¹⁶ find that 64 per cent of all normal pregnant women have generalized edema of varying degree. They believe that the above factors are not the primary causes of edema, although they may play a secondary role. They suspect that, by exclusion, a chemical or hormonal etiology, resulting in retention of water and electrolytes in the tissues, is the cause. Dieckmann¹⁷ states that about 75 per cent of eclamptic women have edema. In his cases, edema was not due to hypoproteinemia. The osmotic pressure was above edema level, and the serum albumin and globulin were normal in composition. He believes the edema is due to changes in permeability of the capillary and cell walls.

Hypertension, another serious abnormality, can be caused by vascular spasm as well as by water retention. Hypertension occurring before pregnancy is usually due to one of the nephritides.

Headache and visual disturbances are believed to be the results of cerebral edema, which follows edema as considered above, and of ischemia of the brain.

PATHOLOGY

Irving¹⁸ gives a thorough review and presents additional descriptions of the pathological findings in eclampsia; he renews the belief that arteriolar derangement affecting all the terminal arterioles is the primary factor in the disease. The organs most affected are the kidneys. He gives Fahr's description of an increase in the size of the glomeruli due to swelling of the capillary walls, and a relative absence of blood cells in the capillary lumens, producing marked local ischemia. Hyaline thrombi are found within the loops. The tubules exhibit albuminous degeneration, which may advance to hyaline formation and fatty changes. Irving states that all glomeruli are not always equally involved; in some cases, individual ones may escape entirely, and the tubules draining these glomeruli are also unaffected. He believes that spasm of the afferent arterioles is the cause of this damage. Bell¹⁹ first demonstrated a massive thickening of the capillary basement membrane. Weiss et al.,¹⁶ describing kidney changes, discovered that the lesions were primarily degenerative and believed that the term "glomerulonephrosis," which has been applied to this condition, seems to be most suitable. They found hyalinization of the

arterioles in some cases. There were no specific changes in the interlobular and arciform arteries.

The liver lesions of hemorrhage, necrosis and fatty degeneration—usually predominant in the periphery of the lobule but also found in the central and midzonal portions—are reviewed by Irving,¹⁸ who places the liver damage on a vascular basis, since thromboses of the radicles of the portal vein or of the small branches of the hepatic artery in the portal space may be observed. Weiss et al.¹⁹ in autopsies on 25 women who died of eclampsia, noted liver lesions in less than half the cases. The lesions varied from mild to severe necrosis and hemorrhage in the peripheral lobules.

Irving¹⁸ describes hemorrhages in the cortex of the adrenal glands and in the capsule and parenchyma of the spleen. In some cases, necrosis in the lymphoid follicles was noted in the spleen; in others, acute inflammation in the spleen was found. Thickening of the arterioles has been observed.

Evidence of arteriolar spasm in the general peripheral circulation, as seen in the capillary loops at the bases of the nails and in the retinal vessels, is also discussed by Irving, and he states that the brain shows ischemic cellular disease, as well as vascular spasm causing necrosis and rupture of the vessel walls.

According to Hertig,²⁰ 50 per cent of uteri show bilateral cornual and subserosal hemorrhages due to arteriolar spasm. He describes the rare "eclampsia of the uterus," that is, toxic separation. He has found capillary thrombosis, petechial hemorrhage and edema at one time or another in all the organs; 60 per cent of eclamptic placentas are infarcted.

Tenney and Parker²¹ describe placental lesions consisting of a premature aging of the placenta. Although 10 to 50 per cent of a normal placenta shows syncytial degeneration, the amount of degeneration in eclampsia is over 50 per cent. This degeneration consists of a clumping together and autolysis of nuclei in the syncytial cytoplasm, clumps of darkly staining masses with no cell outline, and areas of syncytial cells without nuclei. The final stage is the disappearance of all nuclei from the syncytial layer; the villus is surrounded by a thin, irregular mass of hyaline material. Moreover, there is marked congestion of the blood vessels of the villi in the toxemic cases. The blood pressure and the albuminuria closely correlated with the placental findings in 90 per cent of the cases.

STATISTICS

At the Massachusetts Memorial Hospitals, from January 1, 1923, to November 1, 1941, there were

55 cases of eclampsia—emergency, clinic and private—among 22,089 hospital and district deliveries, an incidence of 0.249 per cent, or 1:402. There were 12 maternal deaths, a mortality of 22 per cent (Table 1). Among the fatal cases, there

were 2 vaginal sections, 1 classical cesarean section, 1 manual dilatation and 1 high-forceps delivery of a large baby through a generally contracted pelvis—this last patient, an emergency case, entered the hospital fully dilated and had several convulsions before and after delivery. Four patients died undelivered, 1 died of general peritonitis after a spontaneous delivery following artificial rupture of membranes to induce labor, and 2 died after normal deliveries following conservative treatment. From 1923 through 1931, when operative deliveries were prevalent, there were 32 cases of eclampsia and 9 deaths, a mortality of 28 per cent. Since then, the treatment has been conservative, and there have been 23 cases of eclampsia and 3 deaths, a mortality of 13 per cent. Twenty-nine of the patients were under thirty years of age, and 8 of these died, the mortality being 28 per cent; 26 were thirty years old or older, and 5 died—a mortality of 19 per cent.

Prenatal care is a valuable means of reducing the incidence of and the maternal deaths from eclampsia. It is considered adequate in the clinic when a patient is seen in the fifth month of pregnancy and keeps appointments at least once every four weeks until the seventh month of pregnancy, once every two weeks until the last month, and then once weekly until delivery. It is evident from the results in various clinics that the majority of cases of eclampsia occur in the group of pregnant

women who have had no or inadequate prenatal care (Table 2).

Our statistics agree with most others in that eclampsia is predominant among primigravidas (Table 3).

There was a slight seasonal variation in the incidence of eclampsia in this series, 60 per cent of

In a report of 879 cases, Davis and Harrar³⁰ observed that eclampsia increased through January to a high point in April, with a decrease to a low point in July.

There were two sets of twins from the 50 mothers who delivered, or 4 per cent.

There was 1 case of polyhydramnios in the 55 cases of eclampsia.

Fifty-two babies were delivered from 50 mothers, and 4 mothers died undelivered. There were 13 stillbirths, and 3 babies died after birth, making an uncorrected total of 20 deaths, a mortality rate of 36 per cent. One woman, after subsidence of convulsions and symptoms, went home undelivered, against advice.

The fetal ages when eclampsia occurred are shown in Table 5. Ware and Noblin²³ report in-

cidences as follows: five months and under, 6 per cent; premature, 57 per cent; and full term, 37 per cent.

The times that convulsions occurred are given in Table 6.

SIGNS AND SYMPTOMS

The most frequent signs and symptoms before convulsions in this series were albuminuria (96 per cent), hypertension (93 per cent), edema (82 per cent), headache (71 per cent), blurring of the eyes or spots before the eyes (38 per cent), vomiting (35 per cent) and pain (25 per cent).

The blood uric acid was recorded in 48 cases. The highest readings before, during or after convulsions in 38 patients who recovered averaged 5.8 mg. per 100 cc., and for 10 of the women who died the average was 7.1 mg. per 100 cc., in comparison with Stander's³⁶ figures of 5.6 and 7.6 mg. per 100 cc., respectively. Six of the recordings had readings of 3.5 mg. or below. According to Chesley,³⁷ the absolute level of uric acid is often elevated. More generally, the ratio of uric acid to nonprotein nitrogen is increased, the upper normal ratio being about 1:10. The cause of a rise in uric acid in eclampsia is not known. However, Cadden and Stander,³⁸ in a study of 5 cases,

showed that eclampsia is not associated with decreased excretion of uric acid, and they believe that an elevated uric acid is probably due to impaired destruction of uric acid in the liver.

Routine determinations of the carbon dioxide combining power were not done. Stander and Radelet,³⁹ as well as Cadden and Stander,³⁸ find a decrease in the carbon dioxide combining power. Cadden and Stander emphasize the value of

determining the carbon dioxide combining power and the uric acid. They believe that such data are more indicative of an impending development of convulsions than hypertension, amount of albuminuria or other symptoms are.

TREATMENT

The usual nursing routine in conservative treatment is followed. The patient is placed in a quiet, darkened room. A nurse is always in attendance and she is warned to stop the patient from choking,—because of saliva, vomitus or swallowing the tongue,—to prevent biting of the tongue, and to

When the above treatment fails to improve the patient, a venesection is sometimes done to lower the systolic blood pressure 30 to 50 mm., 200 to 400 cc. of blood being withdrawn.

Besides the routine treatment for pulmonary edema in eclampsia, Dean⁴⁵ recommends bronchoscopy.

As soon as convulsions are controlled and the patient appears improved, and at times when the patient does not improve and it is considered desirable to avoid further delay, the membranes are ruptured. If the cervix is not sufficiently softened, it is packed for twenty-four hours. If the patient

record the blood-pressure and pulse rates hourly. The foot of the patient's bed is elevated, if necessary. A Foley catheter is inserted, and the catheterized urine examined. Blood is taken for determinations of uric acid, carbon dioxide combining power, nonprotein nitrogen, sugar, protein and albumin-globulin ratio. Oxygen is given for cyanosis. Sodium phenobarbital, 5 gr., is given intramuscularly, and Sodium Amytal, 3 gr., is given by mouth or rectum to prevent restlessness (morphine sulfate is occasionally given). Fifty cubic centimeters of a 50 per cent glucose solution intravenously is given slowly to withdraw fluids from the edematous tissues, to increase urinary output and to combat acidosis.^{40, 41} However, dehydration is not a strict rule. If there is oliguria, 500 to 1000 cc. of 10 per cent glucose in distilled water is given intravenously. This is repeated if necessary for the treatment of oliguria or concentration of the blood, according to Davis⁴² and Dieckmann.⁴³ Davis says that when more than 200 gm. of glucose is given rapidly, it causes a very marked glycosuria. Twenty cubic centimeters of a 10 per cent magnesium sulfate solution is given intravenously at each convulsion, and between convulsions if the blood pressure starts rising. Not more than 10 gm. of magnesium sulfate has been given in twenty-four hours. Fischer⁴⁴ reports that it is safe to give up to a total of 8 gm. in twenty-four hours, as a 2.0 or 2.5 per cent solution. Torpin and Coppedge²⁵ give up to 24 gm. in twenty-four hours and 3500 cc. of a 5 per cent glucose solution, with good results. Fluids must be restricted in cardiac cases.

is a primipara with a long, hard cervix and a prolonged labor is feared, or if there is a cephalopelvic disproportion or any other contraindication to pelvic delivery, such as lower-segment fibroids or an amputated cervix, the patient is put in as good condition as possible, blood donors are kept available, and a cesarean section is performed.

Ware and Noblin²³ give digitalis routinely when using magnesium sulfate, because they believe that it should tend to overcome a cardiac depression produced by intravenous magnesium sulfate, since digitalis and magnesium sulfate are physiologically antagonistic in their action on the heart.

Smith and Smith⁴⁶ have used progesterone and estrogen in the treatment of toxemia, but they consider these drugs of little benefit when eclampsia has developed. They advise frequent prolan determinations and early hormonal treatment in pre-eclampsia. They realize that the expense of prolan determinations and hormonal treatment precludes this method at present.

Bryant and Flemming³³ report the use of veratrum viride in the treatment of eclampsia. This drug has been tried by many physicians in the past years. It was used at the Massachusetts Memorial Hospitals in 1912-1913 in doses up to 230 drops by mouth in eleven and a half hours and 360 drops subcutaneously in seventy-two hours, and it did appear to cause a drop in pulse rate; the blood-pressure recordings were inadequate. It was discontinued because it did not seem to give improved results. However, in those years, oh

stetric treatment was radical, including *accouchement forcé*, and little or no treatment for shock; moreover, without intravenous magnesium sulfate therapy, it is difficult to see how any medical treatment could have had a fair trial. Workers at the Cincinnati Hospital, using veratrum viride, intravenous magnesium sulfate, concentrated glucose solutions, sedatives only for extreme restlessness and labor and, rarely, morphine, have treated 120 consecutive cases of eclampsia with 2 deaths, a mortality of less than 2 per cent, which is remarkable.

Veratrum viride is regarded as a powerful drug, and individual susceptibility to the drug is marked. It is described as being a vasodilator, and spasm of the blood vessels is therefore relieved and the blood supply to the tissues is increased.

It seems apparent that veratrum viride should be used with great caution. Until results are obtained from others who are now using the drug according to the routine of Bryant and Flemming,³³ it should not be routinely employed. If the mortality rate of eclampsia can be lowered in other hospitals, it is evident that veratrum viride has an important place in treatment.

SUMMARY AND CONCLUSIONS

Recent theories on the cause and results of eclampsia are reviewed. The physiologic and cellular pathology is discussed, the damage caused to the vascular system being stressed.

Statistics of 55 consecutive cases of eclampsia, with comparative statistics, are presented.

The treatment of eclampsia is outlined. Since the mortality rates show that treatment continues to be inadequate, conservative therapy should be employed until a better method can be substantiated.

DIABETES INSIPIDUS AND PREGNANCY¹

Report of Two Cases

HARRY BLOTNER, M D,[†] AND PAUL KUNKEL, M D[‡]

BOSTON

DIABETES insipidus is comparatively rare, and the combination of this disease and pregnancy is still rarer. It is seldom met with in practical obstetrics, and since 1915 there have been only 3 such cases in approximately 50,000 deliveries at the Boston Lying-in Hospital. From the scarcity of reported cases of the combination of pregnancy and diabetes insipidus, the impression is obtained that very few patients with this disease have children. However, in a thorough study of the literature, it was found that patients with diabetes insipidus have children more frequently than one would expect.¹ At times they are quite prolific, some having as many as eleven children during the course of the disease.

One of the most interesting cases to illustrate this point was reported by Bellot and Brougnart² to the Philomathical Society on October 22, 1791. The patient was a forty-year-old Frenchwoman, who was married at the age of twenty-two. She had had a very considerable thirst from her earliest infancy. While she was single, she drank three pailfuls of water a day. After she was married, two pailfuls were sufficient until she was delivered of her first child, when she returned to her former quantity of three pailfuls and continued it until after the birth of her fourth child. After that period, she drank only two pailfuls in twenty-four hours. When she was pregnant, she had much more thirst than usual. She had eleven children in ten pregnancies. In the presence of a commission, this woman drank 14 liters of water during the space of ten hours. One of Gee's³ patients had nine children. Weil⁴ and his son⁵ studied five generations of a family of 220 members, headed by a man with diabetes insipidus, of whom 35 had the disease. Some of the women with diabetes insipidus had eight or nine children, with normal pregnancies and birth, except that the pregnancies usually increased the symptoms of the disease.

On the basis of a perusal of the literature, the clinical effects of the combination of diabetes insipidus and pregnancy may be classified as follows: aggravation of the disease during pregnancy; transient diabetes insipidus during pregnancy; amelioration of the disease during pregnancy; no effect

of pregnancy on the disease; onset of the disease during pregnancy and persistence after delivery; and transient appearance of the disease after delivery.

Aggravation of Diabetes Insipidus during Pregnancy

A number of reports indicate that the polyuria and polydipsia of diabetes insipidus may be increased by varying degrees and during various periods of pregnancy,⁶⁻¹⁰ as already mentioned. Among 26 members with diabetes insipidus in a family of 73, Ellerman¹⁰ found increased diuresis during pregnancy of the women with diabetes insipidus. In 1 patient, who gave birth eight times, the diuresis increased during each pregnancy from around 10 to approximately 20 liters daily; during the seventh pregnancy, the daily quantity of urine reached 30 liters.

Transient Diabetes Insipidus during Pregnancy

The greatest number of reports on any one of these phases of diabetes insipidus and pregnancy appear in connection with the transient occurrence of the disease during a normal pregnancy.¹¹⁻²⁰ The disease may occur in an apparently normal woman during any stage of pregnancy, from the beginning to near the end of term. However, in most cases, the diabetes insipidus was apparent in the latter half of pregnancy, usually in the fifth or sixth month. Ordinarily, the polyuria and the polydipsia abruptly ceased two or three days after delivery, although in some cases it persisted for as long as seventeen days post partum. There have been cases in which the transient diabetes insipidus occurred in successive pregnancies, in approximately the same months of gestation. In most of these cases, the fluid intake and output increased to about 10 or 12 liters. However, in Edelmann and Kritzman's²² case, the daily urine volume reached a level of 25 liters. Novak's¹⁷ case was of interest because the diabetes insipidus appeared in the course of the first pregnancy and disappeared after delivery; this phenomenon reappeared in the course of ten pregnancies. Gansslen and Fritz¹⁹ presented an unusually interesting case of a healthy woman whose husband had diabetes insipidus. During the terminal part of her first pregnancy, she showed symptoms, which disappeared after delivery. The baby of this pregnancy subsequently had diabetes insipidus. During her second preg-

[†]Associate in Medicine, Peter Bent Brigham Hospital.

[‡]Formerly research fellow in obstetrics, Boston Lying-in Hospital.

nancy, which resulted in a healthy baby, the patient had no polyuria. The authors suggested the possibility that the hormone of the sick child was transferred to the mother during the terminal part of pregnancy and gave her the symptoms of the disease.

Amelioration of Diabetes Insipidus during Pregnancy

Several reports have shown that pregnancy occurring during the course of diabetes insipidus resulted in an amelioration of the disease, and after delivery the polyuria and the polydipsia reappeared abruptly.^{9, 12, 16, 30-34} The most interesting report on this aspect of the problem is that given by Duvoir, Pollet and Cachin,³³ who treated a woman with diabetes insipidus during the course of three pregnancies and observed that the polyuria decreased in the sixth month of each and that the amount of urine became normal during the weeks preceding delivery. However, on the day following delivery, the daily urine increased suddenly to 12 liters, the level before pregnancy. Carter³⁴ noted that a patient had less thirst in the seventh month of pregnancy, and that after a premature delivery, the diabetes insipidus was considerably relieved and remained so during the years of subsequent observation.

No Effect of Pregnancy on Diabetes Insipidus

A number of studies show that pregnancy had no effect on the polyuria and the polydipsia of diabetes insipidus.^{31, 35-40, 65} Some of these patients had urine volumes as high as 16 to 20 liters a day. The patients of Boissard³⁵ and Artaud³⁸ excreted similar amounts of urine without any alteration during pregnancy.

Onset of Diabetes Insipidus during Pregnancy

French³¹ observed a woman who developed diabetes insipidus with a daily urine volume of 10 liters during the fourth month of her fifth pregnancy. The polyuria and polydipsia persisted after delivery. Vickers⁴¹ treated a patient who developed diabetes insipidus with an output of approximately 8 liters when she was three months pregnant. She had urinary retention and, as a result, had to be catheterized; 3250 cc. of urine was obtained. She miscarried a normal three-month-old fetus, and the diabetes insipidus persisted after the miscarriage.

Transient Diabetes Insipidus after Delivery

Transient diabetes insipidus may also appear shortly after delivery. Laurentie and Basiliou⁴² presented the case of a thirty-seven-year-old woman who went through a normal pregnancy. On the day after delivery, the patient suddenly began

to void frequently and to drink with a "rage." Twenty-one days later, she developed violent frontal headaches, photophobia and convulsions. In addition, a transient hypertension appeared. The whole picture was typical of eclampsia; however, there was no albumin in the urine. The fluid intake was as high as 15 liters a day. At one time, the patient had to be catheterized because of a dilated bladder, and 3 liters of urine was obtained. Within six weeks after the onset of convulsions, all symptoms disappeared, and the patient was discharged from the hospital completely recovered.

There are a number of miscellaneous reports on pregnancy and diabetes insipidus, although many of them do not add individual case reports.⁴³⁻⁵³ It appears, however, that the various authors have had experience on this subject. Theses have been published by Jansen⁴⁶ and Schellenberg.⁴⁷ Jansen added a case of a woman who had six deliveries, but the diabetes insipidus appeared only during the last three pregnancies and lasted, each time, until fourteen days post partum. Discussions on this problem have been presented by Lauter and Hiller,⁴⁸ Skrobanski,⁴⁹ Kleinwächter⁵⁰ and Henriet.⁵¹

CASE REPORTS

CASE 1. A 28-year-old woman, who had had diabetes insipidus for over 9 years, had been observed by one of us (H. B.) for 8 years, during which various data were obtained. The daily fluid intake and urine volume usually varied from 10 to 12 liters. The past and family histories were irrelevant. The menses were normal, except that the intramuscular injection of pituitary extract caused painful menses. General physical examinations were normal, except that the patient was about 15 pounds under weight.

The basal metabolic rate was -18 per cent. Lumbar puncture showed a normal spinal fluid. The blood Wassermann reaction was negative. X-ray examination of the skull was negative. The patient required 1 cc. of pituitary extract intramuscularly three or four times a day to reduce her fluid intake and output to about 3 liters. In the preceding 2 years, she had taken powdered pituitary extract intranasally five or six times a day, with relief. Blood studies made before pregnancy were essentially negative, both with and without pituitary extract; some of the results are shown in Table 1.

In 1936, because of various reports suggesting that the administration of estrogenic substance may suppress the diuretic principle of the anterior pituitary gland,⁵⁴ the patient was injected with 20,000 units of amniotin daily for 10 days, without any effect on the fluid intake and output.

The patient had her last menstrual period on June 24, 1940. Her expected delivery date was March 31, 1941. Physical examination was negative except that she weighed only 100 pounds, which was low for her height of 65 inches. The pregnancy progressed normally for both patient and fetus. She had no nausea or vomiting at any time and felt just as well as when she was not pregnant. During the beginning of pregnancy, the daily fluid intake and output were about 10 to 12 liters, the level before

conception, and she took powdered pituitary extract intrasally, with a reduction in these volumes. She felt more movements of the fetus in the 5th month. The blood pressure remained constant at approximately 120/70. X-ray films of the pelvis taken on December 31, at the end of the 6th month of pregnancy, showed a fetus consistent with the date.

The daily fluid intake and output are of unusual interest because they increased to a level of about 13 to 15 liters at the end of the 7th month of pregnancy. When the patient was 7½ months pregnant, the polyuria and polydipsia began to decrease appreciably so that shortly before delivery the daily fluid intake and output were about 3 liters for some days (Fig 1). She went through

was normal. The placenta appeared normally mature.

At birth, the baby's weight was 8¼ pounds, and its height 55 cm. There was an initial loss of 12 ounces, but the birth weight was regained on the 10th day. The baby was breast fed for 31 days. There was inadequate milk supply during this time, but subsequently the mother's breasts dried up rapidly and the baby was given a milk formula. At the age of 6 months, the baby weighed 16 pounds and had one tooth. At 8 months, his weight was 20¼ pounds and his height 74 cm. He had been perfectly normal and had taken a normal amount of liquids.

Various laboratory data were obtained on this patient before during and after pregnancy (Table 1). The re-

4/10/41	101	341	2500	1160	4	64		0	Yes	7.8

a normal labor and was delivered of a normal baby on March 28. The convalescence was normal. The day after delivery, the fluid intake and output increased abruptly to a level of 8 liters, and remained at approximately that level during the subsequent 9 months of observation. These volumes were somewhat lower than those noted before pregnancy. The patient had no edema at any time during or after pregnancy.

It was interesting that during pregnancy the administration of pituitary extract caused a sensation of constriction of the uterus and that as a result, the extract was administered only in small doses. However, when Pitressin, which is supposedly pituitary extract without the oxytocic principle, was administered, it had an antidiuretic effect, without the constrictive action on the uterus. This was shown experimentally by the use of a tocograph which, when properly placed on the abdomen, mechanically records and times the uterine contractions. No uterine contractions were elicited when 0.5 cc of Pitressin was injected subcutaneously. However, normal and rhythmic uterine contractions were obtained when 0.5 cc of pituitary extract was injected.

The placenta weighed 840 gm and measured 23 by 20 by 2.5 cm. The membranes were complete. The cord was attached 2 cm from the nearest placental margin, measured 45 by 1 cm, and was normal on section. The fetal surface was shiny, bluish gray. The maternal surface was intact and very fissured, deep red, dry and soft. The cut surface was deeply congested and gray. Microscopically, there was a moth-eaten and fibrinoid degeneration of the decidua. There were foci of recent hemorrhage on the decidua. The villi were slightly larger than normal ones at full term but were well vascularized. The syncytial nuclear knots were frequent. The stroma was not remarkable. The chorion

sults of the blood volumes were approximately the same as those found during and after pregnancy in the normal woman. In the terminal part of pregnancy, the hematocrit showed a decreased percentage of corpuscles, which increased to 34 per cent shortly after delivery. This compared with 35 per cent obtained a number of times before pregnancy. The venous pressure was equivalent to 10 cm of water. The circulation time was 14 seconds.

TABLE 2 Sugar Tolerance Tests before during and after Pregnancy

DATE	FASTING	1/2 HR.	1 HR.	2 HR.	3 HR.	PITUITARY EXTRACT GLEN

4/9/41	131	145	16	153	145	Yes

by the cyanide method. The basal metabolic rate increased toward the end of the pregnancy to +1 per cent, but within 10 days after delivery, it had decreased to -19 per cent, the level before pregnancy.

Sugar tolerance tests were made during and shortly after pregnancy, and these results were much the same. However, the blood sugar curves were lower than those obtained several years before pregnancy, as shown in Table 2.

CASE 2. A 36-year-old woman was seen in consultation by one of us (H. B.) with Dr. Henry S. Finkel, who treated her during her pregnancies. The family, past and menstrual histories were irrelevant. In 1936, she was delivered of a female child by low cervical cesarean section after a long test of labor, because of cephalopelvic disproportion. There was no polyuria or polydipsia at that time or immediately thereafter.

In the present pregnancy, the last menstrual period began on August 17, 1941. The expected date of confinement was May 24, 1942. General physical examination and routine blood and urine tests were negative. The height was 64 inches, and the weight was 140 pounds. The pregnancy progressed normally until about the 5th

DISCUSSION

A review of the literature indicates that pregnancy may aggravate, ameliorate or not influence diabetes insipidus. In addition, the disease may appear during any stage of pregnancy, disappearing or persisting after delivery. In the first case presented, the polyuria and polydipsia showed some increase in the seventh month of pregnancy and a gradual reduction during the eighth month, so that for some days before delivery the fluid intake and output were about 3 liters. After a

FIGURE 1.

This chart records the daily fluid intake and urinary output during the last two months of pregnancy and after delivery of the patient in Case 1; during this period, no pituitary extract was administered.

month, when the patient began to notice polydipsia and polyuria, which increased progressively as the pregnancy advanced. There was no unusual weight gain. During the last 2 months of pregnancy, the average daily fluid intake and output were about 8000 cc., with maximum and minimum levels of 9200 and 7600 cc. The urine had a specific gravity of 1.002.

On April 27, 1942, x-ray examination revealed a twin pregnancy. Because of the excessive size of the abdomen and the extreme discomfort of the patient, she was delivered prematurely on May 6, 18 days before term, by a low cervical cesarean section under spinal anesthesia. Normal twin boys weighing 5¾ pounds and 7½ pounds, respectively, were delivered. There was a double-ovum, twin, fused placenta.

The convalescence was uneventful except for considerable abdominal distention for the first few days. The polydipsia and polyuria disappeared abruptly after the delivery. The fluid intake and output were normal during the subsequent 3 months of observation. The specific gravity of the urine increased to about 1.015.

normal delivery of a normal baby, the polyuria and polydipsia suddenly rose to about 8 liters, which was somewhat lower than the level before conception took place. In the second case, transient diabetes insipidus appeared in a normal woman in her fifth month of pregnancy and disappeared suddenly after delivery by cesarean operation.

The cause for these variable effects of pregnancy on diabetes insipidus is conjectural. The excretion of water is controlled by a balance of the hormones that diminish and those that produce diuresis. Dexter and Weiss⁵⁶ believe that the mechanisms of oliguria of pregnancy are not uniform in the absence of cardiac or renal disease. The variable effects apparently depend on which of these hormonal forces predominates. It is suggested that

the diuretic or antidiuretic hormone of the fetus may be transferred to some mothers and produce the effects of each in the mother. In the first case presented above, a marked improvement in the diabetes insipidus toward the end of pregnancy was conceivably due to the antidiuretic action of the posterior pituitary lobe of the fetus or to the increased activity of that of the mother. On the other hand, the patient of Gansslen and Fritz²⁰ suggests the possibility that the diuretic hormone of the fetus was transferred to the mother, with the resultant temporary symptoms of diabetes insipidus.

The hormones that diminish diuresis include the hormone of the posterior pituitary lobe. Its value is well established. In addition, follicular hormone, which is normally increased during pregnancy, has been used with success in the treatment of polyuria without pregnancy by Troisier⁵⁷ and Beltrametti,⁵⁸ although this effect was not observed by Blotnei.⁵⁴ The former injected large doses of folliculin into patients with diabetes insipidus and obtained a marked antidiuretic effect. In the first case presented above, no such effect was obtained before pregnancy. Müller³⁰ referred to Scanzoni, who observed a nonpregnant woman with sparse menses and polyuria and noted that when the menses became regular the polyuria diminished.

The diuretic hormones are most probably of anterior pituitary or placental origin. Henriet⁵¹ referred to Lévy-Solal, who presented a polyuric patient with a hydatidiform mole, a condition in which the urinary prolactin is markedly increased. In addition, Lévy-Solal observed a pregnant woman who, in spite of edema, had a significant polyuria. The determination of her daily prolactin excretion gave the enormous figure of 38,000 rabbit units.

The diuretic action of the thyroid hormone is also known. However, in the first case reported above, the thyroid gland probably had no effect on the polyuria because the metabolism increased from -18 to +1 per cent when the urinary volume had dropped to 3 liters a day. After delivery, the patient's metabolism decreased to -19 per cent, and polyuria again developed. The combination of these findings is contrary to those observed by Blotnei and Cutler⁵⁹ in patients with diabetes insipidus whose polyuria was relieved by total thyroidectomy.

The blood volumes determined with Evans blue^{60, 61} were of interest because they were normal in spite of the interchange of huge volumes of fluids. The administration of pituitary extract did not dilute the blood or change significantly the blood volumes either during or after preg-

MEDICAL PROGRESS

MILITARY DERMATOLOGY

C GUY LANE, M.D.*

BOSTON

MILITARY dermatology concerns all cutaneous manifestations that are presented to medical officers under war conditions. Wherever medical officers may be ordered for duty over the present and future world wide battlefronts, they cannot avoid being presented with cutaneous problems. Not all these physicians will have dermatologists available for consultation, and each officer will often be compelled to decide independently on these problems in military dermatology. Many of the diseases are infections caused by animal and vegetable parasites and the pyogenic organisms. The general principles of preventive medicine apply particularly to this group of cutaneous diseases. The medical officer has as his patients healthy young adults. He has the organization and discipline at hand for their control. His duty is to lessen disability and prevent "days lost" from active duty. Detection of disease and the correct diagnosis are the first necessity. With this knowledge, steps may be taken to prevent the disease and to avert its extension on the surface of the patient, its appearance in others and its complications. In the prevention of complications, attention should be given to avoiding not only the complications of the disease but also those of therapy — a significant point in the treatment of cutaneous disease. In the field of cutaneous medicine, as well as in other diseases in wartime, prophylactic measures are essential.

That this prevention is a necessary and vital factor is indicated by a review of the report on skin diseases published by the Surgeon General's office in 1928. This report¹ begins as follows:

Diseases of the skin, exclusive of dermatological manifestations of venereal disease, though ordinarily considered to be of minor importance in so far as danger to life is concerned, are of great importance to an army operating in the field by reason of the noneffectiveness they cause. This was true of past wars and equally so of the World War.

There is no reason to expect that this statement will not be true in the present war, although a full utilization of the knowledge of

cutaneous disease, if such knowledge could be applied, would certainly lessen the duration of disability and the incidence of disease.

The report summarizes the dermatologic figures for the Civil War as follows: itch, 35,236; skin diseases, 38,946; a total of 74,182 cases. Perhaps only these two skin diseases were recognized eighty-two years ago. In the statistics for World War I, the report includes relatively few cutaneous disorders, only about 126,000 cases being listed (Table 1). However, a review of this list indicates very

TABLE 1 Diseases of the Skin and Cellular Tissue Resulting in Primary Admission to All United States Army Hospitals, April 1, 1917, to December 31, 1919¹

DISEASE	NO. OF CASES
Carbuncle	2,330
Furuncle	19,958
Abscess	16,329
Cellulitis	12,874
Trichophytosis	2,813
Ectoparasitism	3,269
Dermatitis	858
Eczema	4,035
Erythema	1,495

Skin diseases	34,134
Other diseases of skin and cellular tissue	20,270
Total	176,375

clearly that many cases could not have been reported and that numerous skin diseases are not discussed. Fungus infections, for example, account for only 2000 cases, and trench feet, in another portion of the volume, for only 2000 cases. There were 3500 cases of ectoparasitism, and yet at the time of the Armistice, pediculosis probably involved 90 per cent of the men in the American Expeditionary Force. Little mention is made of the numerous secondary infections that probably occurred as a result of this infestation. A separate table indicates 18,000 cases in which skin disease was found concurrent with other disease for which hospital admission was made (Table 2). In addition, such diseases as erysipelas, anthrax, trench feet, mycoses, cancer of the skin, purpura and nail defects are not included in the special list of skin diseases.

The statement quoted above regarding noneffectiveness is borne out by the number of days lost during the war (Table 3). The figures include

Reprints of articles in this series are not available for distribution but the articles will be published in book form. The current volume is *Medical Progress Annual Vol III 1942* (Springfield Ill no 3 Charles C Thomas Company 1942 \$5.00).

*Clinical professor of dermatology Harvard Medical School chief of Department of Dermatology Massachusetts General Hospital.

only the diseases mentioned in the portion of the report entitled "Skin Diseases," omitting the cases found concurrently or those in the list of general diseases. It is obvious, therefore, that over 2,000,000 days of service were lost by reason of cutaneous affections to the Army alone during World War I.

Syphilis is also an incapacitating disease, this report³ stating that there were 67,026 admissions for syphilis and 9665 other cases in which syphilis was found when the soldiers were admitted for

TABLE 2. *Concurrent Diseases of Skin and Cellular Tissue Found in Cases Admitted for Other Diseases to All United States Army Hospitals, April 1, 1917, to December 31, 1919.*¹

other reasons. It is of interest that the admissions for syphilis represented only 1.85 per cent of the admissions to hospitals, and yet the total number of days lost from duty was over 1,927,201, and 143 deaths were charged to syphilis.

The incidence of skin diseases in the Navy confirms the gravity of these diseases in a military organization. In a report by Sulzberger, MacClatchie and Parsons⁴ citing statistics of the Medical Corps of the United States Navy, 14.8 per cent of all admissions for disease between 1929 and 1938 included men with skin diseases and syphilis. It is probable that a number of skin cases were omitted from these figures, which do not include, of course, the ambulatory patients. One and a quarter million days in hospitals were lost on account of these diseases. Skin diseases represented the third commonest cause of admission in this period, with a rate of 22.6 per thousand men, acute catarrhal fever ranking highest and gonorrhea second. These are peacetime figures and do not consider the inevitable increase of certain parasitic infections in time of war. Of individual diseases, scabies had the highest admission rate and trichophytosis next, and trichophytosis ranked highest in number of sick days per year per thousand men.

In addition, a personal letter from a dermatologist at one of the naval stations shows that 13 per cent of the total admissions to the hospital in the first eight months of its existence were on the dermatologic service. This figure includes all the common diseases of the skin in stages that rendered the service men temporarily unfit for duty. Thirty per cent of these admissions were for fungus infections of the skin, and 20 per cent were for scabies. It is stated that preventive methods are in force at this particular station, and yet these admissions continue. It is furthermore of interest that almost all the patients admitted to the hospital had already been overtreated in their particular outfits. This comment of overtreatment has come to me from several other sources. The complication may occur because of the failure to make a proper diagnosis or to estimate the tolerance of

TABLE 3. *Days Lost from Active Duty in United States Army by Patients with Diseases of the Skin and Cellular Tissue (April 1, 1917, to December 31, 1919).*²

DISEASE	DAYS LOST
Carbuncle	43 000

Total	1 848,900

an individual skin, or because of the desire to clear up the existing skin trouble quickly by strong measures.

It is not possible to discuss all the alterations in the cutaneous surface that may appear as a result of these diseases, but perhaps some service may be rendered by a review of some of the salient features of diseases with cutaneous manifestations that appear before medical officers under war conditions. For convenience, they have been divided into ten groups.

CUTANEOUS DISEASES CAUSED BY ANIMAL PARASITES

Parasitic diseases, both animal and vegetable, take the highest toll of disability from Army and Navy personnel. Other aspects of the parasitic diseases are often more serious than the infestation itself. Overtreatment, which has already been mentioned, constitutes a factor that definitely increases disability. The secondary pyogenic infections occurring as a complication of these parasitic dis-

eases at times assume serious aspects and are frequently a cause of prolonged disability. Perhaps more critical are diseases that the animal parasite may carry, so that the occurrence of such infestations is of particular interest from the standpoint of general preventive medicine.

Scabies ranks high in the list of these diseases that cause disability. When the disease is well marked, there is little difficulty in diagnosis. The increased itching at night, the characteristic locations of small papules and excoriations about the axillas, hands, wrists, genitals, waist and posterior upper thighs and the finding of burrows are sufficient evidence. The minimal infections in the early stages often offer considerable difficulty in the making of a definite diagnosis. In a case that has been overtreated, possibly with a mild secondary infection, a clear-cut diagnosis of scabies, pediculosis or a minimal urticaria is frequently difficult for an experienced dermatologist, and it is quite a problem for the average medical officer. Under military conditions, it is probably safer to treat such patients if there is sufficient suspicion of scabies; one should bear in mind, of course, the possibility that a dermatitis—a complicating and disabling factor—may result from therapy. Secondary pus infections of scabies are significant, and one should remember that the *Treponema pallidum* may enter through scabietic lesions.

Last year, several articles on scabies were written from the British standpoint. Buxton² brought out the fact that the interval from the egg to the adult female can be less than eight days and that the first egg may be laid twenty-four hours after maturity. The female is thought to lay approximately two eggs a day, perhaps a total of forty to fifty eggs. There may be an interval of eight to ten days between infestation and the development of symptoms. The disease usually comes from another human being, but animal infestations have occasionally been discovered, although it is not possible to distinguish morphologically between the human and animal parasites.

Carter⁶ reviews the treatment of scabies with a sulfur lather tablet, but only two groups of children were treated. MacKenzie⁷ reviews the treatment of two groups of patients, one painted by a benzyl benzoate emulsion and the other by a sulfur ointment, indicating that the benzyl benzoate emulsion provided rapidity of cure, almost immediate relief from itching, ease and speed of application, and absence of unpleasant aftereffects.

Mellanby⁸ experimented with the transmission of scabies to volunteers. Of 63 persons living in underclothes and sleeping in blankets used by

known scabietic patients, only 2 became infected. On the other hand, a small number of experiments showed that scabies was conveyed by relatively slight personal contact. It is suggested that venereal contact provides better opportunity for the transmission of scabies than clothing.

Benzyl benzoate has had further favorable reports. Ingels⁹ used a mixture of benzyl benzoate, sapo mollis and isopropyl alcohol in 90 patients, with good results, and Goldman¹⁰ devised a cream modification that has proved effective, although it is more expensive than sulfur ointments.

In the Navy, Nolan¹¹ has used a soap paste, containing 18 per cent sulfur, that is efficient and inexpensive, but a three-day course of treatment is necessary. Rotenone has been reported to be successful in scabies, but Epstein¹² believes that it is ineffective in the presence of a complicating pyoderma.

Although these methods are successful in the treatment of scabies, they do not appear to be any more speedy and efficient than the present twenty-four-hour treatment with Danish ointment,¹³ if the preparation can be compounded correctly and made available for use by the armed forces at the places where it is needed.

In any discussion of scabies, consideration must be given to the atypical cases, which may be difficult to detect, and to the minimal infestations, which are not sufficient to bring the patient to sick call. Search should always be made for contacts and sources of infestation, to eradicate them. Sterilization of clothing (bed and body) is essential. Too much emphasis cannot be placed on early detection and, perhaps, on the periodical inspection of troops for minimal lesions if a case or cases are discovered in a particular camp.

Pediculosis, of course, should be easy to recognize. The finding of nits in the scalp or the pubic region on careful inspection quickly confirms the diagnosis. The body cases, with minimal signs, are often difficult, and yet they may remain as a source of infestation to others. The secondary infections, as a result of infestation, will undoubtedly be markedly increased in the tropical cases, and antiseptic therapy, as well as antiparasitic therapy, should be undertaken. A 2.5 per cent solution of phenol applied for one hour and followed by combing with a fine-toothed comb is a satisfactory form of treatment for the scalp variety. The pubic cases clear quickly following shaving of the entire affected area. A shower and sterilization of clothing are necessary. Delousing stations, with bathing facilities and clothing sterilization, will adequately clear the body type.

TROPICAL SKIN DISEASES

Tropical skin diseases will need consideration by American physicians more than in any other war. Many varieties of cutaneous disease are due to fungi, protozoa and metazoa. The manifestations vary with the particular section of the world to which a medical officer may be assigned, and no definite review of these diseases is possible. Strong's¹⁴ recent revision of Stitt's well-known book is worth studying for those ordered to tropical countries. The secondary pyogenic infections of these infestations will undoubtedly be a further cause of disability. Adequate precautions will need to be taken to prevent the invasion of this country by these diseases as the troops return home.

DISTURBANCES CAUSED BY VESICANT CHEMICAL-WARFARE AGENTS

Chemical-warfare agents caused considerable injury and some deaths during the last war. The principal vesicants are mustard gas and lewisite. Mustard gas, recognized clinically by the garlic-like odor and brownish oily stains on the clothing, is of low volatility, and may remain in the open for ten days—longer in the woods and in cold weather. After a latent period of two to six hours, the gas causes erythema with itching and burning, and the absorption of the liquid begins in three minutes if it contacts the skin. Vesicles and bullae are rapidly produced and heal slowly. In contrast to mustard gas, lewisite, which has a geraniumlike odor, has a shorter latent period,—fifteen to thirty minutes,—and there may be more sneezing and nasal irritation. The bullae form more quickly, and because of the arsenic content, varying degrees of arsenic poisoning are produced by the cutaneous lesions. With both, if the patient is seen early, the removal of clothing for decontamination is necessary, and the skin should be treated with solvents (kerosene, gasoline and so forth) or oxidizing agents (bleaching-powder paste, dichloramine T, hydrogen peroxide and sodium bicarbonate).

Goldman and Cullen²² have recently reviewed the effects of these agents and their treatment. The subject is also presented in a seventy-five-page booklet issued by the Office of Civilian Defense.²³ The later treatment of burns by these agents is well outlined by MacCollum.²⁴ If assigned to front-line duty, the medical officer should be familiar with the protective methods against these agents, their first-aid care, their aftercare and the details of decontamination.

SYPHILIS

Syphilis deserves further comment. Early primary and secondary syphilis will undoubtedly be seen. It should be detected early and treated ade-

quately. The cases should be sent to special centers for treatment until noncontagious, and provision should be made for uninterrupted continuous treatment²⁵ in accordance with accepted procedure. If the war lasts five years, attempts to conserve manpower by adequate early treatment are particularly necessary. At present, the new five-day treatment²⁶ or one of its modifications is not for routine use. A clinic might be set up, however, in some large center, where, under the direction of physicians experienced in the proper technic, selected cases could be given the advantage of this method. The part that the medical officer can play in the control of venereal disease is valuable from the standpoint of preventive medicine. Early detection and diagnosis, tracing and elimination of the source of the infection, and adequate treatment and follow-up are the keystones in the prevention of disability due to syphilis and other venereal diseases.

Chancroids may be confused with the primary lesion of syphilis. Dark-field examinations, until the diagnosis is clear, and serologic follow-up should be done to prove that syphilis was not acquired at the same time. Evidence is increasing that sulfanilamide is beneficial in many cases of chancroidal infection.^{27, 28}

In the differentiation of penile lesions, one should remember the value of skin tests—the Ito-Reinstierna test for chancroid^{29, 30} and the Frei test for lymphopathia venereum. In the treatment of the latter disease, sulfanilamide has proved of value.³¹

OTHER SKIN DISEASES OF YOUNG MEN

Numerous cases of other relatively common diseases will occur in the young men inducted into the Army or Navy as essentially healthy persons. There will be many cases of dermatitis from the many contacts made in the field or in camp. A dermatitis may appear anywhere, it may be obstinate and may cause much disability, and much detective work, to ferret out the exact causal factor, may be required. It is essential that soothing treatment be given at the beginning, or when the diagnosis is in doubt. Light³² has well outlined the therapy of acute undiagnosed manifestations on the skin.

Overtreatment was mentioned above, but it deserves emphasis again. Dermatitis from therapy, whether it is due to self-medication without a proper diagnosis, to improper medication from an error in diagnosis, to the excessive application of an appropriate remedy or to hypersensitivity of the patient, causes more visits to the dermatologist than any other single skin disease. Miller, Ayres and Alderson³³ point out that many patients seek relief because of such treatment and not because of their primary complaint. A longer period of disability

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-FIRST ANNUAL MEETING

House of Delegates, May 11, 12 and 13

(Concluded)

After commending the committee for its excellent work, Dr. Sycamore, of the Committee on Officers' Reports, recommended that the House of Delegates express its sincere appreciation of the work of the Committee on Maternity and Infancy, and extend its congratulations to the members of this committee for their high standard of achievement; it was voted to adopt this portion of the report.

At this point, the reading of the reports was interrupted to permit a discussion by Dr. Burroughs, who spoke on the New England Institute. This is strictly an educational institute and is intended to provide some theoretical training in public health to local health officers, to the workers of various local volunteer agencies, to the staff of the state departments of health and to any others who may be interested. It is particularly valuable because many of these people have no opportunity for formal training in public health.

In the ordinary rotation, next year will be the year for the institute to come to New Hampshire. It was held in New Hampshire in 1926. From 1930-1938, it was dropped, but it was revived in 1939 in one section, and in 1940, it was fully revived, and has been held every year since then. The 1942 session has just been held in Providence, Rhode Island, with an attendance of 972 from the six states of New England.

The State Board of Health voted to recommend to the Governor and Council that this institute be held in New Hampshire in 1943; that recommendation was laid before the Governor and the Council for consideration.

At the meeting held at Hartford, Connecticut, in 1940, the Connecticut State Medical Society was one of the co-sponsors, and was responsible for one of the sectional meetings, which occupied the afternoon of one day of the institute.

Dr. Burroughs asked if, in the event that this meeting should be held in New Hampshire next year, the New Hampshire Medical Society would be interested in co-sponsoring and in putting on a sectional meeting. No expense would be entailed by the Society, because the State Board of Health would handle the cost, as well as the details, on behalf of the Secretary of the New Hampshire Medical Society.

President Dolloff asked what being a sponsor entailed.

Dr. Burroughs replied that it constituted having the name printed on the programs and officially endorsing the institute.

Dr. D. G. Smith moved that the Society be a co-sponsor of the New England Health Institute, the details of the participation of the Society to be left to the Committee on Public Health.

Dr. Metcalf stated that Dr. Burroughs had told him that the State Board of Health would be very glad to arrange the program. However, Dr. Metcalf did not know the health officials who ought to be on the program. There are three days, and the sponsor is responsible for half a day. The Board of Health, in co-operation with the Committee on Public Health, could pick out the men who are going to speak and place them on the program.

The motion presented by Dr. Smith was then seconded and carried.

Dr. Parsons asked if any delegate knew of any members of the county societies who would be interested in taking a course covering the medical aspects of chemical warfare, at either the University of Cincinnati or another teaching center.

The report of the Committee on Medical Economics was then presented.

Report of the Committee on Medical Economics

The chairman of the Committee on Medical Economics, Dr. Clarence E. Dunbar, has been called into active service with the Army Medical Corps, and the work has been carried on since his departure by the remaining two members. We have greatly missed Dr. Dunbar's wise counsel in our deliberations.

The committee has directed its attention to three major problems the first of which is a medical-service corporation.

In pursuance of the instructions received from the House of Delegates, your committee has conferred with Attorney Sulloway regarding an enabling act to permit the establishment by the New Hampshire Medical Society of a Medical-Service Corporation in New Hampshire. Attorney Sulloway has drawn up a proposed act, with due reference to the recommendations of your committee and the laws and regulations governing the operation of the insurance corporations in New Hampshire, and a copy is appended to this report. Your committee has scrutinized this act and believes that it embodies the provisions that have been

proved by experience in other states to be essential to the successful working of such a plan. We wish to commend the careful and conscientious effort that Attorney Sulloway has given to this task.

Your committee recommends that the New Hampshire Medical Society approve the proposed Act Governing Medical-Service Corporations and instruct the Committee on Public Relations to secure its introduction into the next session of the Legislature.

It is to be emphasized that the passage of the act by the Legislature would in no way obligate the Society to embark on a program of prepayment medical care but would merely establish the legal setup under which such a program could be instituted at any time in the future when such a step should seem advisable.

The work of the National Physicians' Committee for the Extension of Medical Service is of continuing importance and will be of greater value as time goes on. The trend toward governmental regulations of medical practice was gaining rapid momentum until interrupted by the war emergency. No thoughtful observer doubts that this trend will be resumed at the conclusion of the war and will be accelerated in fact by the economic problems of the postwar period. The preservation of the personal relation between physician and patient which we believe to be the most efficient and effective form of medical care depends largely on the efforts of the medical profession to educate the public to awareness of its value. The National Physicians' Committee has proved itself an effective instrument for this purpose, and as such deserves the support of the medical profession.

The budget of the National Physicians' Committee would be met by a contribution of one dollar from each member of the American Medical Association, and this seems a small enough amount for each of us to invest in his own future. Your committee recommends that the House of Delegates request each component county society to make such a contribution to the treasurer of the New Hampshire Medical Society, to be forwarded to the National Physicians' Committee as a contribution from the physicians of New Hampshire, and that a committee of the Society be constituted to co-operate with the National Physicians' Committee in its educational work and in the securing of the necessary contributions for its support. The Committee on Public Relations might logically be designated to carry out this task.

Your committee has wrestled with the problem of compensation for the physician in service, but it believes that the more it wrestles the more it becomes enmeshed in the coils of this knotty question. It is certain that no recommendation can be formulated that will be universally applicable to every situation. In some circumstances it would be only just that part of the fees collected from the patients of a colleague who is in the service should be remitted to him. Such action must be left however to the judgment and conscience of each physician. Consideration is being given to the possibility of issuing a limited license to any physician coming into the State to take over the practice of one who has entered the service—such a license would be valid only for the duration of the emergency. Your committee has no specific recommendations to make, however, regarding this complex problem.

The Committee on Medical Economics was instructed at the last meeting of the House of Delegates to investigate the problem of medical care for low income families in rural communities. This problem however has apparently been solved by the changing economic situation and

the State Grange believe that there is no need for such an investigation at the present time.

LESLIE K. SYCAMORE *Acting Chairman*
RICHARD W. ROBINSON

Dr Sycamore moved that the Committee on Public Relations be instructed to secure the introduction of the enabling act into the next session of the Legislature.

This motion was duly seconded and was carried.

Dr Sycamore then moved the adoption of the portion of the report relating to the work of the National Physicians' Committee.

Dr Metcalf asked how this money would be turned over to the National Physicians' Committee.

Dr Sycamore replied that the treasurers of the county societies would turn it over to the treasurer of the New Hampshire Medical Society.

The motion presented by Dr Sycamore was duly seconded and carried.

Dr Sycamore then moved that the House of Delegates approve the principle of limited licensure of physicians who move to the State to replace those who enter the armed forces.

This motion was duly seconded and carried.

President Dolloff presented the report of the Committee on Mental and Social Hygiene.

Report of the Committee on Mental and Social Hygiene

There have been no new developments in New Hampshire in the field of mental and social hygiene during the last year nor are there likely to be for some time to come. Specialists in the field of mental hygiene are making what contribution they can to the effort to prevent another billion dollar expense to the Government such as that resulting from the previous war because of the comparatively large number of prepsychotics and other misfits taken into the Army.

The institutions expect to take a severe setback in both their intramural and extramural activities. With the competition offered by the Federal government in munitions plants and other employing agencies the institutions can hardly be expected to retain or replace good intelligent employees who can easily obtain work at more pay and fewer hours elsewhere.

Under ordinary circumstances we should encourage early commitments but under present conditions we suggest that no one be sent to the institutions who can be cared for elsewhere.

Since the microcephalic patients usually have ossified cranial sutures at birth the officials at the State School are convinced that medical schools should prepare physicians to recognize the grosser degrees of mental defect at birth and that they should be reported to the Board of Health as such. Although notification is made of a case of measles which lasts ten days no record is made of the birth of an idiot, who is a living first mortgage on the State for life.

This state has an excellent sterilization law and if a similar approach to the subject is maintained it should re-

main a very useful aid in our battle with mental deficiency and mental disease.

Since there is no particular connection between mental and social hygiene, and since each calls for a different line of thought and investigation, we recommend that a separate committee for social hygiene be created by the House of Delegates.

The New Hampshire Hospital Association has a committee on legislation, whose function it is to keep track of proposed legislation affecting hospitals, but there does not appear to be any similar committee of this Society.

CHARLES H. DOLLOFF, *Chairman*
BENJAMIN W. BAKER
JOHN B. McKENNA

Dr. Sycamore stated that the Committee on Officers' Reports agreed that social hygiene is a separate field from mental hygiene, and moved that questions of social hygiene be placed under the jurisdiction of the Committee on Public Health, and that, at the next revision of the by-laws, the words "and Social" be struck from the title of this committee.

Dr. Dye asked whether the revision of the by-laws should not be referred to the Committee on Constitution and By-Laws.

Dr. Sycamore answered in the affirmative, and amended his motion accordingly.

The motion was then duly seconded and carried.

Report of the Committee on Tuberculosis

It is with deep regret that the Committee on Tuberculosis records in this report the death on January 29, 1942, of one of its members, Dr. Robert M. Deming, late superintendent of the New Hampshire State Sanatorium at Glencliff. Dr. Deming had been a member of this committee for many years. He had served the State of New Hampshire as superintendent of the sanatorium at Glencliff from 1922 until his death.

For twenty years, Dr. Deming had given unstintingly of himself in devoted service to his patients. Under his leadership and administration, the sanatorium had been developed into one of the Nation's best for the treatment and cure of tuberculous patients. He was a valiant worker in the campaign for the early detection, prevention and treatment of the disease. His death is a serious loss to the tuberculosis campaign in our state.

It is interesting that within the past few years an active campaign has been under way for the organization of tuberculosis committees in state and county medical societies throughout the Nation. Only recently, the Pennsylvania State Medical Society announced the organization of a state tuberculosis committee in its membership.

It is probably true that the New Hampshire Medical Society can claim the distinction of having organized the first tuberculosis committee in a state medical society. This committee was appointed in 1914.

Throughout the years, your committee has worked with the following objectives in view: to stimulate active interest in combating tuberculosis on the part of physicians in general practice; to establish a harmonious and helpful relation between the medical profession and official and voluntary organizations engaged in the control of tuberculosis; and to keep the profession informed concerning resources in the State for the diagnosis, preven-

tion and treatment of the disease and of progress toward its control and eradication.

The encouraging progress that has been made in combating tuberculosis in New Hampshire is due in large measure to the active support and aid of the members of the New Hampshire Medical Society.

In 1940, the tuberculosis mortality in the State fell to a new low figure of 21.2 per 100,000 population. In 1916, the death rate was 114.5. Only six states in the Nation had a lower death rate than New Hampshire—Utah, Wyoming, Iowa, Nebraska, Idaho and North Dakota. According to a statistical study made by the National Tuberculosis Association of the percentage of reduction in tuberculosis death rate among the states of the union in the period 1916 to 1940, New Hampshire presented the greatest reduction—81.5 per cent. This splendid result is due to the united effort of our physicians, sanatoriums, health and school departments, tuberculosis agencies and the people throughout the State.

As always, our problem is to find tuberculosis cases in all stages of the disease, best of all in the earliest stages and even before activity is present.

An excellent piece of tuberculosis case finding is being carried on at the Selective Service Induction Center in Manchester. An essential part of the examinations at this induction center is an x-ray examination of the chest for every man. We are not permitted to give out figures regarding the number of men called, or other statistics, but it can be stated that because of these chest x-ray examinations, tuberculosis is being kept out of our military forces and that the entire program is aiding materially in the discovery of tuberculosis in the State. All men rejected because of tuberculosis are reported to the State Board of Health, and follow-up service is provided by the New Hampshire Tuberculosis Association.

For some years, your committee has emphasized the great value of the chest x-ray film in the discovery of tuberculosis. It is known that the lesions can be seen on the chest x-ray film before signs can be heard by the stethoscope. We again urge on the members of the New Hampshire Medical Society frequent use of the chest x-ray examination. The New Hampshire Tuberculosis Association is ready to provide chest x-ray films for persons referred by physicians when these persons are unable to pay for them.

We urge prompt examination of all members of the family when a case of tuberculosis is found, since in a household where an open case has been discovered, we usually find that all members are positive tuberculin reactors.

We urge at least a tuberculin test for all persons caring for children. This should be a routine procedure for nursemaids, governesses and others in contact with children.

Bed rest continues to be emphasized in treatment. In most sanatoriums, on admission of patients, all are on bed-rest regime for study by the physicians and decision about activity of the disease.

In addition to rest treatment, various forms of chest surgery, such as pneumothorax, phrenicectomy, phrenicotomy and thoracoplasty, continue to be emphasized as aids to cure of the disease.

In this connection, it seems advisable for the best interests of the chest surgical services in our two sanatoriums that this program of treatment be developed under the direct charge and supervision of one chest surgical service.

By means of this procedure, possible chest surgical cases would be reviewed oftener and followed up more thoroughly so far as the carrying out of recommendations for treatment is concerned. Also, the responsibility would be more definitely allocated. Furthermore, in conjunction with this plan, a definite program of providing costs of treatment could be developed.

One of the members of the committee made a study this spring in Michigan of the chest surgical services in that state. The program is carried out along the lines we have suggested as being advisable in New Hampshire. In Michigan, the program has been thoroughly developed and is now in operation for some years, and appears to be working successfully.

For some time, it has appeared that the policy of restricting admissions to one of the two sanatoriums in the State to far-advanced pulmonary tuberculosis cases has not been satisfactory. Theoretically, a sound policy in practice it has resulted in lowered morale in the institution and reluctance of patients to enter it. During the past three years, in this one sanatorium 75 deaths occurred—almost half within sixty days after admission.

During the past year, the New Hampshire Tuberculosis Association has been making a study of this problem. In the summer of 1941, the association sent a questionnaire to the executive secretaries of the state tuberculosis associations of the United States asking information regarding presence of a similar problem in their respective states and how it had been solved. Forty-four states sent replies. Some few were working on the problem, all the others had had similar experiences and had solved it by dividing their states into districts or sections and by admitting patients in all stages of the disease to the sanatorium in the district or section in which they live. It is our opinion that this policy should be carried out in New Hampshire.

The New Hampshire State Sanatorium and the New Hampshire Tuberculosis Association continue to offer their services in the interpretation of chest x-ray films sent to them for diagnosis.

The Nation is engaged in a great world war. Today tuberculosis is more than a threatening shadow. It is a definite obstruction to victory, acting like sand in the gears of the production and fighting machine. Longer hours of labor and increased mental and physical strain tend to increase tuberculosis. The infection is still wide spread among our people. Tired bodies may permit ever lurking germs to attack the lungs successfully.

There must be no letup in the campaign against the disease. In fact, the fight must be carried on with ever greater aggressiveness to hold the gains won.

Your committee wishes to express its appreciation for the wholehearted assistance and encouragement accorded to it by the members of the New Hampshire Medical Society.

ROBERT B. KERR, *Chairman*
M. DAWSON TYSON

Dr. Sycamore, after commending the committee for its work, moved that the House of Delegates approve the recommendations of the Committee.

This motion was duly seconded and was carried.

Dr. Robertson read a letter from the American Medical Association Bureau of Medical Economics, addressed to the secretary of the Society, regarding H. R. 4476, now in the Senate Committee on Military Affairs. He moved that

the recommendation contained in the letter be seconded by the Society, that such notices be sent to the Committee on Military Affairs, and that a personal note be sent to Senator Bridges, who is a member of the Committee on Military Affairs.

This motion was duly seconded and carried.

Dr. Robertson then read a letter concerning the proposed tax on hospitals and colleges, which may be enacted. The tax referred to would affect the incomes of educational and charitable institutions derived from funds received from real-estate investments. Dr. Robertson stated that the Committee on Communications and Memorials recommended that the secretary of the Society be instructed to notify the congressmen and senators that the Society, as a body, protested any abridgment of the exemptions now allowed by Section 101 of the revenue laws regarding charitable and educational institutions.

This motion was duly seconded and carried.

Dr. D. G. Smith then made his report as delegate to the American Medical Association.

Report of the Delegate to the American Medical Association

The ninety-second annual session of the American Medical Association was held at Cleveland, June 2-6, 1941. It was a well attended and interesting meeting, at which your delegate served as a member of the Committee on Executive Session. The Distinguished Service Award was given to James Ewing of New York, and Fred W. Rankin of Lexington, Kentucky, was chosen president-elect. There was considerable discussion of specialty boards for the general practitioners, and there was also a demand for a new section of the scientific assembly for this group. It was decided to have an experimental session for general practitioners in the Section on Miscellaneous Topics at the next session. This is to be held at Atlantic City, June 8-12, 1942, and is to be known as the Pan American Session.

A report was made of the indictment and trial of the American Medical Association, and it was voted by the House of Delegates that the Trustees be instructed to direct counsel to appeal the judgment based on the verdict of guilty against the Association.

Medical preparedness was the chief topic of discussion at the meeting. A resolution requesting the Surgeons General of the Army and Navy to make women physicians eligible for reserve commissions was disapproved, although the spirit of American medical women in offering their services to the Government was applauded. Payment for services of the physicians serving with the Selective Service System was disapproved. A resolution was adopted requesting the establishment by the federal government of a Procurement and Assignment Agency. It was proposed that this agency should continue the work of the Medical Preparedness Committee of the American Medical Association, and that it should have authority for the selection of physicians who would be necessary for immediate duty and who would be called from civilian practice to serve with the armed forces. Such an agency has been established as known as the Procurement and Assignment Service, and is in operation at the present time. Its function is to procure physicians for the

armed forces, and at the same time to be certain that the medical needs of the civilian population are taken care of.

DEERING G. SMITH

Dr. D. G. Smith then presented the report of the Committee on Medical Preparedness.

Committee on Medical Preparedness

The Committee on Medical Preparedness has continued its co-operation with the Selective Service System and has approved all appointments of physicians as examining physicians and members of the medical advisory boards. Most of the work of this committee has been taken over by the Procurement and Assignment Service, with Dr. Deering G. Smith as state chairman; Drs. Ezra A. Jones and John P. Bowler serve with him. This service has the twofold purpose of securing physicians for the armed forces and providing for the care of the civilian population. The availability for active service of each physician in the State is to be determined. No federal appropriation of money has been made to carry on this work, although it is hoped that such an appropriation will be made in the near future. Some state medical societies are going to continue to finance the project, whereas others are planning to accept federal funds. Your committee desires the decision of the House of Delegates.

An intensive recruiting drive is about to be started in this state, to secure fifty physicians for the army before July 1, 1942. Captain E. L. Wiemers, representing the Office of the Surgeon General, and Lieutenant R. G. Vedeler, representing the Office of the Adjutant General, will be working with Dr. Smith, and it is expected that commissions will be granted within a week of the time of application.

DEERING G. SMITH, *Chairman*

EZRA A. JONES

CARLETON R. METCALF

Dr. Sycamore, acting for the Committee on Officers' Reports, recommended that the House of Delegates express to Dr. Deering G. Smith its sincere appreciation of the whole-hearted and unselfish enthusiasm with which he had devoted himself to the exacting and often thankless duties of the Procurement and Assignment Service, giving freely of his time and energy, although frequently at no inconsiderable inconvenience to himself and detriment to his own practice.

For the work of the Procurement and Assignment Service, a large number of detailed records must be kept; a great deal of correspondence is entailed, and the frequent use of the telephone and telegraph is necessary. Obviously, no budgeting of such items is possible. Dr. Sycamore therefore recommended that the Treasurer be instructed to defray all necessary expenses incident to the work of the committee, and that reimbursement be made for expenses already incurred.

After much discussion, a motion by Dr. Robertson—that the Government be allowed to pay the expenses of the Procurement and Assignment Service—was lost. Dr. Sycamore then moved that the expenses incurred by Dr. Smith be paid out of the general funds of the Society.

This motion was duly seconded by several of the members present and was carried.

Dr. Gray then spoke on the status of chiropractors in New Hampshire. He stated that at the spring meeting of the Rockingham County Medical Society, the delegates were instructed to bring before the meeting a recommendation, which was as follows:

The Rockingham County Medical Society is unalterably opposed to the practice of chiropractic. The kindest thing one can say for it is that it is quackery.

It is obvious that only by pressure politics could chiropractic have obtained a foothold in New Hampshire. It can be ousted only by pressure politics. This will mean that the Society is willing to expend money and employ legal talent to conduct a successful fight.

The delegates of Rockingham County are instructed to bring this matter before the New Hampshire Medical Society. As a Society, we favor a study of this problem, with a view to definite action in the coming legislature. We favor any legitimate action, even at considerable expense, that can bring about a revocation of chiropractic in New Hampshire.

Dr. Metcalf stated that the chiropractors usually have two or three members in the Legislature, and that the recommendation proposed would probably only make enemies and would not succeed in forcing the chiropractors out of business.

Dr. H. O. Smith then stated that the detailed report of the Trustees would be given on Wednesday afternoon, but that some financial matters should be touched on at this meeting, which was probably the most largely attended meeting of the House of Delegates. He then made the following remarks:

As most of you are aware, all the invested funds of our Society have, until last July, been deposited in various savings banks. A year ago, the Board of Trustees thought it wise to diversify our investments further, the determining factor being the strong effort then being made by the national authorities to sell savings bonds of various types.

Our purchases were of Series G bonds, a registered current income security paying 2½ per cent a year in semiannual installments, the funds being taken from accounts and banks that seemed to us advisable.

You should know that this transfer was made without the loss of interest for a single day, and that these bonds are yielding a slightly higher rate of interest than was being paid by the banks. But, in view of present conditions, the important thing is that the New Hampshire Medical Society now has \$10,000 invested in the future of America.

Dr. Sanders then spoke as follows:

Last year, I had the honor of being elected vice-president at the meeting of the House of Delegates. Because a number of our physicians will enter the armed services, I believe that I shall be working to the limit of my strength next year; therefore, and because the last two winters have been rather trying to me, I shall not be able to assume the burden of the duties

of president of the New Hampshire Medical Society, and I do not wish to be a candidate for the office of president. This year will be a legislative year, and it is sometimes hard to get from Claremont to Concord. I believe that I should not take this office.

Dr Wilkins expressed his regret that Dr Sanders declined the office.

Dr Gray stated that an important matter brought up by the Rockingham County Medical Society was the practice by naval doctors, particularly in Portsmouth. Those men stationed at the Navy Yard are engaging in civilian practice in their hours off, and they wanted to know what their status was. Dr Gray had written a letter to the Board of Registration to see whether or not a license was required. In the Army, medical men have definite instructions not to indulge in civilian practice unless they are stationed in their own communities. That apparently was not so in the Navy, because some of the men in Portsmouth are indulging in practicing medicine. The members of the Rockingham County Medical Society wanted to know if the House of Delegates could take some action or make some recommendation.

Dr Burroughs stated that he had discussed the matter with the naval authorities about three years ago, when the present marital blood test legislation was passed. He presented the senior medical officer in Kittery with a set of applications for the Board of Registration in Medicine, for the reason that a license from the Board of Registration in Medicine is required in the people who certify for marriage purposes. The senior medical officer told Dr Burroughs that the Navy was considering following the precedent already established by the Surgeon General of the Army, namely, that medical officers of the Army were prohibited from engaging in civilian practice in the vicinity of the Army posts. No such regulation had been issued by the Surgeon General of the Navy, but it was anticipated that such a regulation might be issued, and in the meantime, the Surgeon General's policy was definitely to discourage such activity on the part of the naval officers. The medical officer returned the set of blank applications with the comment that the Navy doctors had no use for them.

Dr Burroughs further stated that the Attorney General had informally ruled that, since the Navy Yard in Kittery is actually located on the borders of New Hampshire, on the line of New Hampshire and Maine, a commission in the Navy should be regarded as having the same effect as a license in the adjoining state, hence, a naval medical officer situated at Portsmouth, holding a commission

from the Navy, should be considered authorized to practice medicine in New Hampshire, under that exception in Section 18 of the Medical Practice Act, which states that so long as he does not establish an office or appoint a place to meet patients in New Hampshire, any physician practicing on the borders of New Hampshire and duly licensed in his own jurisdiction does not require a license in New Hampshire.

Dr Grice stated that the Belknap County Medical Society requested the New Hampshire Medical Society to grant to Edwin P. Hodsdon of Lakeport, the privilege of affiliate membership with the Society, and the privilege of nonpayment of dues. Dr Hodsdon was given a gold medal for fifty years of practice at this annual meeting.

Dr H. O. Smith moved that Dr Hodsdon be made an affiliate member of the New Hampshire Medical Society.

This motion was duly seconded and was carried.

The first meeting of the House of Delegates was adjourned at 10:55 p.m.

* * *

The House of Delegates convened at the Hotel Carpenter, Manchester, on May 12, 1942, at 8:30 a.m. with Speaker Timothy F. Rock, of Nashua, presiding.

The following members answered the roll call:

The President, *ex officio*

The Vice President, *ex officio*

The Secretary-Treasurer, *ex officio*

P. R. Hoyt, Laconia (alternate for Lyall A. Middleton, Plymouth)

Emil J. Gage, Laconia (alternate for Richard W. Robinson, Laconia)

W. J. Paul Dye, Wolfeboro

Francis J. C. Dube, Center Ossipee

Walter F. Taylor, Keene

Norris H. Robertson, Keene

Leander P. Beaudoin, Berlin

Lewis C. Aldrich, Jefferson

Everett C. Campbell, Woodsville

Arthur W. Burnham, Lebanon

Leslie K. Sycamore, Hanover

George V. Fiske, Manchester

Deering G. Smith, Nashua

H. O. Smith, Hudson (appointed as alternate for Charles H. Cutler, Peterborough)

George C. Wilkins, Manchester (appointed as alternate for Clarence L. Dunbar, Manchester)

William P. Clough, Jr., New London

Clinton R. Mullins, Concord

Frederick S. Gray, Portsmouth

Anthony E. Peters, Portsmouth

Louis C. Theobald, Exeter

Albert E. Barcomb, Farmington

George G. McGregor, Durham

Bernard P. Haubrich, Claremont

Addison Roe, Newport

The Speaker declared a quorum present, and asked for further reports of standing committees.

Dr. Sycamore repeated the recommendations of the Committee on Medical Economics. Dr. Metcalf inquired what was meant by the words, "to replace," in the report.

Dr. Sycamore answered that, if a physician goes into a town because somebody else has gone out, such a residence is not necessarily a definite arrangement. The recommendations present one possibility of trying to protect the man who leaves his practice.

Dr. Dye stated that a ruling from the Attorney General's office concerning such limited licensure would be required. Under the present law, there is no provision for making any type of limited licensure. Dr. Dye also said that at present the Medical Practice Act requires that a man be a citizen of the United States to practice and to receive a license in New Hampshire. About the only type of person to whom a limited license could be given would be a refugee physician. In Dr. Dye's opinion, it would be very difficult and impractical to give any qualified physician a limited license to practice in New Hampshire. In other words, if a man is a graduate of a first-class medical school, having had two years preliminary education in a college approved by the Board of Registration in Medicine and one year's internship, and has passed the examinations, there would be no way of limiting his license. One disadvantageous point is that a refugee physician, if granted a limited license, might go into a community, and it is a well-known fact that every physician who practices in any community builds up a certain amount of following, so that after a year or two of practicing in that community, there would always be a group of people who would bring pressure to bear that his license be retained and that he be privileged to continue to practice there.

Dr. Sycamore stated that the Committee on Medical Economics was thinking of the refugee-physician problem, in presenting this subject for discussion. It was in an attempt to anticipate such pressure that it was deemed advisable to discuss the problem.

Dr. Wilkins asked whether this question would not finally come down to an agreement between the officials of the Procurement and Assignment Service in the State and the State Board of Registration in Medicine.

Dr. D. G. Smith was of the opinion that the resolution does not apply only to refugee physicians: there is a great possibility that it may be necessary to transplant doctors from the larger cities,—for example, from Massachusetts to New Hampshire,—to take care of some of the rural areas.

He agreed that the matter should be taken care of by the Board of Registration in Medicine, under the war emergency clause and the present statutes. He believed that the committee's idea was to obtain an opinion from the House of Delegates regarding whether or not they would approve limited licensure; such a statement would help the Board of Registration in Medicine somewhat in solving this problem.

Dr. Metcalf asked how, under the present law, a limited license could be issued.

Dr. D. G. Smith replied that the Board of Registration in Medicine would practically dictate it, under a war clause. He pointed to a section in the by-laws that requires applicants for examination for licensure to meet certain conditions: two years of premedical training, graduation from an approved school, a year's internship, citizenship and so on; the last part of that section reads: "The provisions of this section may be suspended in whole or in part by order of the Board on account of war or other threatened or existing national calamity."

So that, in the final analysis, the Board may license anybody it wishes to license. The position of the Board up to the present time has been not to let down the bars in any particular case—so far as letting in men from substandard schools and men who have not had any premedical education is concerned.

Dr. Taylor moved that the House of Delegates approve the limited license, in principle.

This motion was duly seconded and was carried, with one dissenting vote.

Dr. Dye, reporting for the Committee on Amendments to the Constitution and By-Laws, stated that various matters, largely of a technical nature, were referred to the committee. It was recommended that Chapter VIII, Section 6, of the by-laws be amended to read in full as follows: "Section 6. The Committee on Medical Economics shall consist of three members." Previously, this particular section read: "Section 6. The Committee on Medical Economics shall consist of three members, one of whom shall be elected annually for a term of three years."

This change was suggested to make it a standing committee and not a rotating committee.

Dr. Dye moved the adoption of the proposed change.

This motion was duly seconded and was carried.

Further changes recommended were as follows:

We recommend that Chapter VIII, Section 10, be amended to read as follows: "The Committee on Mental Hygiene shall consist of three members, whose duties shall be to study this special subject, co-operate as far as possible with the heads of the state institu-

tions under medical supervision and report to the society."

The only change is in the striking out of the words "Social Hygiene" and changing the plural to the singular.

I move the adoption of this amendment to the by-laws, regarding Section 10 of Chapter VIII.

In Section 12, it was a technical matter, to make this a standing committee instead of a rotating committee.

We recommend that this section be amended to read as follows: "The Committee on Medical Education and Hospitals shall consist of three members."

I recommend and I move a change in the heading of Section 1, Chapter VIII, naming one Committee as the Committee on Mental Hygiene, omitting "and Social."

With reference to Chapter I, Section 5, regarding membership, this matter was brought up because Dr. Hodsdon, who was a member of the New Hampshire Medical Society, without being a member of a component medical society, became a member prior to the formation of the county societies and now wishes to be made an affiliate member.

I should like to read the proposed amendment to Section 5 completely, as follows: "Any physician who has been a member of this Society for a continuous term of fifteen years and is either not less than sixty-five years of age or totally disabled, on personal application or on the request of his county society, may be made an affiliate member by a majority vote of the House of Delegates. Affiliate members shall have the same rights and privileges as other members of the Society, but shall not be required to pay dues."

Unless some one has any other particular question in mind regarding members, that completes our report on amendments to the by-laws.

We were asked to give an opinion regarding the clarification of the membership qualifications. I shall first read Section 2, of Article IV, of the Constitution, which has to do with the composition of the society: "The members of the Society shall be the members of the component county medical societies and the present members of the New Hampshire Medical Society."

In the first place, there is no specification that residence in New Hampshire is necessary for membership. Secondly, men who were not previously members of the Society prior to the formation of the county medical societies must now be members of a component county medical society before being accepted by the State Society.

Dr. Sanders, referring to the question of eligibility to membership in a county medical society, stated that Dr. Amsden, of Ackworth, had come to New Hampshire from New York and had applied for membership in the New Hampshire Medical Society. He continued:

I found, in looking up the matter, that it was required that a member be licensed in New Hampshire and that he be in active practice. Those requirements, I think, come through the constitution and by-laws that each county society is supposed to adopt on recommendation of the New Hampshire Medical Society.

I wondered if that was the regular practice of county societies in admitting members to the county membership—that is, a man could not merely reside, and not be in active practice or licensed, in the State, and still be a member of a county medical society.

Dr. Amsden took out a New Hampshire license, and is in practice in the State. He is a retired psychiatrist, and I think perhaps did not intend to practice in the State; however, he is practicing somewhat to keep up his membership in the American Medical Association. He gave up his New York State membership, and had to have some county membership to keep up the American Medical Association membership.

Dr. D. G. Smith moved that Article XII be deleted from the Constitution, explaining that such an action must be proposed at one annual session and then acted on at the succeeding annual session.

This motion was duly seconded and was carried.

Dr. Wilkins moved that Article XIII of the Constitution be made Article XII.

This motion was duly seconded and was carried.

Dr. Dye moved that since the by-laws had been amended to the effect that a present member of the Society may apply for affiliate membership, Dr. Hodsdon, who had written to the Society, be made an affiliate member of the New Hampshire Medical Society.

This motion was duly seconded and was carried.

Dr. Dye stated that this was not in the nature of a motion and that the delegates might want to discuss the question. He referred to Dr. J. Dellinger Barney, who had relinquished his residence in New Hampshire and wondered what his membership status would be. So far as the committee could determine, he could follow one of two courses. If his county society retained his membership, Dr. Barney could continue to be a member of the Society, since there is no provision in the constitution of the Society that a man must be a resident of the State to be a member of the Society. Should he not continue as a member of his county society, by virtue of the local county constitution, under Section 4, Article IV, he could be proposed by the House of Delegates as an honorary member of the Society.

Dr. D. G. Smith cautioned the Committee on Constitution and By-Laws to be sure that it did not conflict with the constitution of the Cheshire County Medical Society and with the constitution and by-laws of the American Medical Association, since he believed that such a conflict might occur:

The model constitution of the county society says that a doctor, to be eligible for membership, must reside and practice in the county in which he is applying for membership, with the exception that men on county lines and state lines in adjoining counties or states can belong to that county society.

Dr. Robertson inquired about members who practice in New Hampshire and are members in Massachusetts and have kept up their Massachusetts membership through the years.

Dr. D. G. Smith answered that, strictly speaking, such members can belong only to one county and one state medical society.

Dr. Sycamore said that there should be a general ruling that would cover these cases and that, in his opinion, a simpler solution would be to make them honorary members; the question of a conflict with the American Medical Association rulings would then be avoided.

Dr. Dye moved that any physician who is not a resident of New Hampshire have his individual status regarding membership in the New Hampshire Medical Society, subject to the recommendation of his component county medical society.

Dr. Sycamore asked if the American Medical Association or the component societies had the final authority.

Dr. Rock declared that he did not know who had the final authority.

Dr. Dye stated that, apparently, certain members of the House of Delegates wanted a ruling regarding cases like that of Dr. Barney, and that he had therefore moved that each county society decide the matter.

Dr. D. G. Smith stated that the question involved a double representation: a man belongs to one county society, and his membership counts as a quota toward the state society in electing a delegate; the same thing would be true if he belonged to two county societies in the State. His name would be added to their membership lists, making a quota for the members necessary to have an additional delegate to the House of Delegates. In the American Medical Association, he is listed in two different states; therefore, he contributes to New Hampshire's quota for a delegate and he contributes to the Massachusetts quota.

After further discussion, the motion previously made by Dr. Dye was seconded by Dr. Fiske and was carried.

The second meeting of the House of Delegates was adjourned at 10 a.m.

* * *

The House of Delegates convened at the Hotel Carpenter, Manchester, on May 13, 1942, at 8:30 a.m., with Speaker Timothy F. Rock, of Nashua, presiding.

The following members answered the roll call:

The President, *ex-officio*

The Vice-President, *ex-officio*

The Secretary-Treasurer, *ex-officio*

Earl J. Gage, Laconia (alternate for Richard W. Robinson, Laconia)

W. J. Paul Dye, Wolfeboro

Francis J. C. Dube, Center Ossipee

Lewis C. Aldrich, Jefferson

Everett C. Campbell, Woodsville

George V. Fiske, Manchester

Deering G. Smith, Nashua

H. O. Smith, Hudson (appointed as alternate for Charles H. Cutler, Peterborough)

George G. Wilkins, Manchester (appointed as alternate for Clarence E. Dunbar, Manchester)

William P. Clough, Jr., New London

Frederick S. Gray, Portsmouth

Albert E. Barcomb, Farmington

Bernard P. Haubrich, Claremont

Addison Roe, Newport

Dr. Dye reported for the Committee on Nominations, as follows:

OFFICERS

President: Timothy F. Rock, Park R. Hoyt and Arthur W. Burnham.

Vice-President: Ralph W. Tuttle, James W. Jameson and Fred Fernald.

Councilor for Coos County (five-year term): Richard E. Wilder.

Councilor for Carroll County (five-year term): W. J. Paul Dye.

Trustee emeritus: Henry O. Smith.

Trustee for three years: Clarence O. Coburn.

House of Delegates: speaker, Charles H. Parsons; vice-speaker, George F. Dwinell.

Necrologist: Henry H. Amsden.

Delegate (American Medical Association): Deering G. Smith.

Alternate Delegate (American Medical Association): Emery M. Fitch.

Delegates to New England Societies (1942):

Maine: Leopold T. Togus, Lawrence R. Hazzard.

Vermont: Harry B. Carpenter.

Massachusetts: Wallis D. Walker, W. J. Paul Dye.

Rhode Island: Reginald F. DeWitt, Ellsworth M. Tracy.

Connecticut: John F. Gile, James E. Bovaird.

STANDING COMMITTEES

Amendments to Constitution and By-Laws: James B. Woodman, W. J. Paul Dye, Frederick S. Gray.

Child Health: Colin C. Stewart, Jr., Travis P. Burroughs, Franklin N. Rogers.

Control of Cancer: George C. Wilkins, Ralph E. Miller, George F. Dwinell.

Maternity and Infancy Robert O Blood, Benjamin P Burpee, Marion Fairfield.

Medical Economics Leslie K Sycamore, Richard W Robinson, Francis J C Dube

Medical Education and Hospitals John P Bowler James W Jameson, Herbert L Taylor

Mental Hygiene Charles H Dolloff, Benjamin W Baker, John B McKenna

Public Health Travis P Burroughs, Anthony E Peters, Harris E Powers

Public Relations The President, The Vice President The Secretary Treasurer, Robert J Graves, Ezra A Jones

Publication Carleton R Metcalf, John F Gile, Emory M Fitch

Scientific Work Carleton R Metcalf Frederick P Scribner, Sven Gundersen

Tuberculosis Robert B Kerr, M Dawson Tyson, Clarence O Coburn

Medical Preparedness Deering G Smith Ezra A Jones, Carleton R Metcalf

The report was accepted Dr Timothy F Roel of Nashua, was elected president

Dr James W Jameson, of Concord, was elected vice president

Dr Dye, for the Committee on Nominations, recommended a standing vote on one other nomination on the slate—for trustee emeritus, Dr Henry O Smith, of Hudson

The Secretary was instructed to cast one vote for Dr Henry O Smith as trustee emeritus, this was done, and he was declared duly elected

The Secretary was instructed to cast one ballot for the remainder of officers and committee members as nominated, this was done, and all were declared duly elected

Dr Metcalf moved a vote of gratitude to the members in Manchester who had arranged the details of the meeting, it was so voted

Dr Wilkins then presented the report of the Committee on the Control of Cancer

Report of the Committee on the Control of Cancer

The Committee on the Control of Cancer has sent to every physician in New Hampshire the usual three letters of information regarding specific phases of cancer diagnosis or treatment. The first letter was devoted to prostatic carcinoma, a condition more frequently found than is generally realized, the second briefly discussed diagnosis and treatment of cancer of the mouth and the last called attention to the valuable lay educational work performed by the Women's Field Army, stressed the value of urging people to have periodic physical examinations and urged more education of the public in recognizing the significance of irregular uterine bleeding as

well as the urgency for immediate thorough examination in the event of rectal bleeding. Too many physicians are still too reluctant in carrying out the necessary examinations required to determine the cause of bleeding in these two conditions

During the year, requests for full sets of these letters, sent since 1934 to New Hampshire physicians, have been received from cancer committees in Maine, Vermont, Kansas and Georgia, and from the American Society for the Control of Cancer

In 1935, at the request of the Cancer Commission, the State Board of Health made cancer a reportable disease. The physicians of the State and the hospitals were appealed to by both the commission and the Board of Health to report all cases of cancer coming to their attention. The Pathological Laboratory at Hanover co-operated to the extent of mailing to physicians a partly filled out form with each positive cancer report. In 1941, the Board of Health at the suggestion of the commission, repealed this ruling because, during the six years that cancer was reportable it was found that there were reported only about 50 per cent as many cancer cases as there were cancer deaths and the reported cases came almost entirely from the cancer clinics. The Cancer Commission suggested this repeal because it seemed fruitless to continue an effort when such a lack of co-operation on the part of physicians was evidenced. Without full co-operation, there is no way of ascertaining how many active cancer cases there are in the State.

The diagnostic clinics and treatment centers supervised by the Cancer Commission have continued their excellent work, and about sixty members of the New Hampshire Medical Society are regularly taking active part in this clinic service. There is still much evidence of ignorance, apathy and delay on the part of patients in spite of the efforts of the medical profession and the widespread distribution of small pamphlets carried each year into every city, town and village by the Women's Field Army. Last year, ninety-five thousand pieces of literature were distributed and the New Hampshire leaflets are now printed in English, French, Polish and Greek. We urge all physicians of the State to read the reference book on cancer, which was sent to every physician in the State in 1940 by the Women's Field Army.

In Massachusetts the intensive cancer control campaign took ten years of constant effort before the mortality rate dropped definitely downward. The New Hampshire program is now in its seventh year, and we hope soon to observe tangible evidence of the effectiveness of medical and lay education combined with improved surgical and radiologic treatment.

Much credit should go to the alertness of the majority of the physicians in the State for their keenness and ability in recognizing cancer early and inducing patients to seek early treatment. A minority of physicians unfortunately still have a lackadaisical attitude toward thorough and adequate physical examination, early indications of cancer and the methods of making early diagnosis. These men need education but they are probably the ones who throw our letters into the wastebasket unread.

Your committee has spent \$44.35 for printing, stationery and postage in sending out nearly two thousand letters, the balance of \$5.65 having been returned to the treasurer. We request an appropriation of \$50.00 for the coming year.

GEORGE C WILKINS, *Chairman*
HOWARD N KINGSFORD
GEORGE E DWINE

Dr. Sycamore, for the Committee on Officers' Reports, recommended that the requested appropriation of \$50.00 be approved.

This motion was duly seconded and was carried.

The report of the Committee on Medical Education and Hospitals was then presented.

Report of the Committee on Medical Education and Hospitals

POSTGRADUATE MEDICAL EDUCATION

The fifth annual meeting of the Associated State Postgraduate Committees was held in Cleveland in 1941 in conjunction with the meeting of the American Medical Association. The meeting of this committee was attended by Dr. Deering G. Smith as our representative. The new chairman is Dr. Frank R. Ober, of Boston. The New England member of the Executive Committee is Dr. Frederick T. Hill, of Waterville, Maine.

This committee has been working for some five years in the attempt to co-ordinate the activities of the various state committees on medical education and hospitals, and the program being assumed by them is a steadily more pretentious one. In this connection, at their last meeting, it was voted that an assessment of \$50.00 be made against each state to provide funds for the activities of this committee. It is the opinion of Dr. Smith, who attended this meeting, and of several others, that the activities of postgraduate education in the State are too limited and will without doubt be more limited in the near future to warrant this expenditure by the Society at this time. This reason leaves out altogether the question whether or not such assessment should be on the basis of population rather than a fixed, uniform figure. It is therefore the belief of this committee that the State assessment be not recommended to the Society at this particular time.

COMMONWEALTH FUND FELLOWSHIPS

A year ago, we rendered a brief review of the activities of the Commonwealth Fund Fellowships in this state for the preceding five years through which they had been operating. It is to be expected under present conditions that there has been less interest in this activity this year as measured by the response to the circularization of the

membership of the New Hampshire Medical Society. To date, there have been requests for application blanks from only eight members of the Society, and appointments have not yet been announced by the Commonwealth Fund.

There seems to be little more that can be done in the way of calling the attention of the membership to these fellowships, which seem to be so generous and intelligent in their conception, and it is to be hoped that their value will not be lost sight of in the exigencies of the times in which we are now living.

JOHN P. BOWLER, *Chairman*
JAMES W. JAMESON
HERBERT L. TAYLOR

Dr. Amsden read the report of the necrologist.

Report of the Necrologist

The following deaths have occurred since the last annual meeting:

NAME	ADDRESS	DATE DECEASED
Abbott, Charles B.	Penacook	March 24, 1941
Cheever, Nathaniel F.	Greenfield	June 15, 1941
Cobb, Joseph J.	Berlin	July 15, 1941
Daudelin, Alfred	Nashua	September 21, 1941
Deming, Robert M.	Glenciff	January 28, 1942
Hinds, Wm. H. W., Jr.	Milford	March 10, 1942
Kittredge, Frank E.	Nashua	July 8, 1941
LaFrance, Albert J.	Laconia	March 12, 1942
Lamb, Zenas F.	Keene	April 28, 1941
Marks, Homer H.	Berlin	April 11, 1941
Noyes, Walter F.	Colebrook	May 24, 1941
Potvin, Victor E.	Claremont	December 10, 1941
Sanborn, Benjamin E.	Manchester	October 3, 1941
Webber, Norman B.	Manchester	February 22, 1942
Weinberg, Philip B.	Whitefield	August 27, 1941

HENRY H. AMSDEN

Dr. Rock expressed appreciation to the members of the House of Delegates for their assistance in carrying on these meetings.

The third and final meeting of the House of Delegates was adjourned at 9:20 a.m.

**CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITAL**

ANTE MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28341**PRESENTATION OF CASE**

A fifty-year-old man was admitted to the hospital because of cough and fever.

During the week prior to admission, the patient suffered with a "head and chest" cold characterized by a great deal of coughing productive of small amounts (not over a teaspoonful a day) of whitish sputum. He was seen by his physician on the evening prior to entering the hospital. At this time, he was coughing and vomiting, and there was some right-lower-quadrant pain associated with the bouts of coughing. There was no hemoptysis, and no chills or chest pain. Rales were audible at the posterior base of the left lung, and a murmur, believed to be early diastolic, was heard at the apex. A urine specimen was said to have contained many blood cells and much albumin.

The family history was irrelevant.

The past history was unremarkable except for an accident that occurred one year previously, when the patient fell from a truck and sustained a fractured skull. He was unconscious for twelve days, and since then he had suffered with severe left frontal headaches, dizziness and tinnitus.

Physical examination revealed a well-developed man in no distress who coughed frequently, bringing up a thin, white sputum. The chest was barrel shaped. Examination of the heart was negative, although one observer reported a systolic murmur audible to the left of the sternum and a sharp pulmonic sound. There was some impairment of resonance at both lung bases posteriorly. The percussion note was hyperresonant, with some dullness over the left lower lobe posteriorly. Sticky rales were audible in the left chest, most marked at the bases. A few persistent inspiratory rales were audible in the left infraclavicular region anteriorly. There was deep tenderness in the right upper quadrant, but no abdominal masses were felt. There was also left costovertebral tenderness. There was prominent clubbing of the fingers.

The blood pressure was 138 systolic, 80 diastolic. The temperature was 100.6°F, the pulse 96 and the respirations 24.

Examination of the blood revealed a hemoglobin of 107 gm., and a white-cell count of 8600 with

67 per cent polymorphonuclears, 5 per cent large lymphocytes, 12 per cent small lymphocytes and 16 per cent monocytes. The blood Hinton test was reported doubtful and, when repeated, was unsatisfactory. The nonprotein nitrogen was 60 mg per 100 cc. Examination of the urine revealed a specific gravity of 1.012, a +++ test for albumin and 100 red blood cells, 10 white blood cells and 10 epithelial cells per high power field. No acid fast bacilli or other pathogenic organisms were found in the sputum. A blood culture was negative.

X-ray examination of the chest showed symmetrical and diffuse linear and hazy density of both lungs, more marked at the bases. Both lung roots were enlarged, and the right side of the supracardiac shadow was moderately prominent. The heart was not definitely enlarged but was triangular—prominent across the base. The costophrenic angles were hazy, particularly in the posterior portion.

The patient complained of fever and sweating during the entire period of hospitalization. There was no chest pain, and no change in the amount of coughing. Repeated urinary examinations revealed a persistently low specific gravity, a +++ test for albumin, rare hyaline and cellular casts, many white blood cells and large numbers of red blood cells. The urine cultures revealed no growth.

Intravenous pyelograms showed no excretion of the dye. Small areas of dense calcification were found in the region of the upper pole of the right kidney. There were small flecks of calcification in the right pelvis close to the sacroiliac joint. The kidneys were normal in size and shape. The liver edge was lower than normal, and a soft-tissue mass, apparently the spleen, overlaid the upper pole of the left kidney.

On the fifth day, there was less moisture in the lungs. The nonprotein nitrogen had risen to 111 mg. per 100 cc. two days later. On the ninth hospital day, while reaching for a bedpan, the patient suddenly noted pain in the right hand. The hand became cold, and the patient could not dorsiflex it. No brachial or radial pulse was felt; there were faint arterial pulsations in the axilla. On the following day, the pain was somewhat relieved. The radial pulse gradually returned. The blood pressure on this day was 82 systolic, 72 diastolic, in the right arm and 130 systolic, 70 diastolic, in the left.

A Congo red test revealed 70 per cent retention of the dye in the serum after an hour.

On the thirteenth day, the spleen was felt two or three fingerbreadths below the costal margin. The strength in the right hand had improved considerably. An x-ray film of the chest showed

little change. The diffuse, hazy density appeared to have cleared slightly.

Two and a half weeks after admission, the patient complained of slight pain in the left shoulder, which became progressively worse, particularly when he took a deep breath. A faint rub synchronous with the heart beat was audible over the entire precordium. The heart sounds were distant, but the radial pulse was regular and strong. The blood pressure was 140 systolic, 85 diastolic. That evening while on a bedpan, the patient suddenly began to breathe stertorously and expired.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: It seems very clear to me that this patient had a bacterial endocarditis, that he had multiple emboli with infarcts, and that he had some type of renal failure, all of which led to sudden death. The questions to be answered are: What type of endocarditis was it? What type of renal failure? What was the cause of the apparent pericarditis? What was the immediate cause of death? I should like to have Dr. Hampton tell me, if he will or can, whether the x-ray film of the heart shows any suggestion of previous long-standing heart disease, perhaps congenital heart disease or some other type.

DR. AUBREY O. HAMPTON: I think the heart is definitely enlarged. It is triangular and the curve of the right auricle is high. The aorta is small, and the pulmonary vessels are dilated. The thing that bothers me most is whether there are also enlarged lymph nodes at both lung roots aside from the dilated pulmonary vessels. The heart has more the appearance of mitral disease than congenital heart disease. There is no fluoroscopic note of how large the left auricle was. This is the lateral view, but there is no oblique view, which would help more than the lateral. This shadow to the right of the mediastinum is longer and lower than the usual azygos node that one sees in sarcoid and lymphoma. It could be the vena cava, I suppose, but there must be something in addition to the vena cava there. When one sees the enlarged spleen, one wonders if these enlarged nodes are associated with that—provided they are enlarged nodes. I am not too happy about it. There is also what appears to be edema of the lung and, in addition, diffuse linear density in the lung, which could be connected with enlarged lymph nodes, as in sarcoid. I think that there was a definite heart lesion, and that there probably were enlarged lymph nodes.

DR. RICHARDSON: What about this?

DR. HAMPTON: That is a focus of calcification, but I do not know where it is.

DR. RICHARDSON: I was not paying too much attention to it.

DR. HAMPTON: It shifts in relation to the kidney cortex. Here it is about 2.5 cm. from the margin, and there is 1.5 cm. I assume that it is outside the kidney. It could be in the gall bladder, but it does not look like either gallstone or renal stone. The kidneys show very poor function. This is a 30-minute film with intravenous dye, and as you see, there is nothing in the bladder. The right kidney is low, and the edge of the liver is not so low as the edge of the spleen.

DR. HARWOOD: Could the heart shadow be simple dilatation?

DR. HAMPTON: I do not believe so. It has an abnormal shape. Simple dilatation would maintain a normal shape, I think.

DR. RICHARDSON: I shall disregard the calcification, which is a dangerous thing to do with all these calcium experts around. There is x-ray evidence that there may have been a preceding heart lesion, and the picture is somewhat suggestive of the possibility of mitral stenosis, if I understand Dr. Hampton correctly. That would give at least a background for subacute bacterial endocarditis. I was prepared to make this diagnosis in the absence of evidence of preceding heart disease because I thought that the picture was very clear. Assuming for the moment that I am right about it, if this was bacterial endocarditis, what organism was involved? It seems to me that one of the acute types—a beta-hemolytic streptococcus or pneumococcus—would have grown out in a culture. If the blood picture is correctly reported, the presence of an increased number of monocytes without a definite polymorphonuclear formula is suggestive that this was not an acute type, but more likely one due to the alpha-hemolytic streptococcus. I believe that this patient had bacterial endocarditis, with vegetations on the valves infected by the *Streptococcus viridans*.

So far as the type of renal failure is concerned, we know, accepting that diagnosis, that nephritis is a common complication of bacterial endocarditis, and I believe something like 90 per cent are glomerular and 10 per cent embolic; therefore, one ought to be in favor of the glomerular type. However, certain things lead me to suspect that the patient had embolic nephritis, or even large renal infarcts. One is that he had costovertebral tenderness, which is not very definite evidence. Another is that he had evidence of emboli in the systemic circulation. There was an embolus in the blood vessels of the arm, and it seems to me that there was enough suggestion of emboli for embolic nephritis to be considered; it is even quite possible that the patient had large renal infarcts. I therefore think that is so, and that he had uremia. I believe the uremia caused the pericardial friction rub. I do not know about that sequence of

events. I suppose that pericarditis can be associated with reactivation of rheumatic heart disease, but I think one might reasonably see that this patient had uremic pericarditis.

The cause of death seems to me most likely embolic, and since many of the embolic phenomena have been in the systemic circulation, it seems more likely that the patient had a cerebral embolus than a pulmonary embolus. I wondered whether this could have been some type of cancer and whether all these phenomena were due to cardiac invasion, possibly with the production of thrombus and embolus. There is a great deal going on in the chest that Dr. Hampton does not like. I do not like it either, but I shall not change my original diagnosis on the basis of the x-ray films. I shall say that there was not any type of malignant tumor. I do not know what the calcification was. If the patient had had a previous infarct, he might have had calcium in the infarct. In bacterial endocarditis, infarction is very common. One would expect infarcts in many organs especially the lungs, spleen and kidneys, and peripheral infarcts elsewhere. Therefore, I make a diagnosis of subacute bacterial endocarditis, probably engrafted on chronic rheumatic heart disease, alpha-hemolytic streptococcus infection and embolic nephritis, probably with large renal infarcts, uremic pericarditis, and a large cerebral embolus as the immediate cause of death.

DR. FULLER ALBRIGHT: Are you disturbed that the kidneys were small? They are usually not small with large fresh infarcts.

DR. RICHARDSON: I think it is very reasonable. I think there was endocarditis for some time before the three weeks mentioned in the history.

DR. ALBRIGHT: How about the sterile urine? Embolic nephritis is not associated with sterile urine.

DR. RICHARDSON: I do not know. I do not believe that is necessarily true.

DR. ALBRIGHT: I do not know that it is, either, as a matter of fact.

DR. F. DENNETTE ADAMS: Why do you think that a large cerebral embolus, rather than a pulmonary embolus, accounted for this very sudden death? Do you not expect cerebral hemorrhage to last a few hours?

DR. RICHARDSON: Yes; my reasoning was that there was one in the arm, and it seemed more on the systemic than the pulmonary side. Accordingly, I put it there. I thought the description was not quite that of ordinary pulmonary embolism, but there is really nothing to go on.

DR. MAURICE FREMONT-SMITH: Is the x-ray film consistent with pericardial fluid?

DR. HAMPTON: With the exception of the lung roots, yes. If the patient had perfectly normal lungs and pulmonary vascular shadows, it would

be quite consistent with it, but apparently he had something going on in the pulmonary vascular system for a long time before that. The heart is not very large, so that the whole thing can be explained by mitral stenosis.

DR. ALBRIGHT: You do not know the calcium and serum protein?

DR. TRACY B. MALLORY: No.

DR. HAMPTON: Another thing—the chest films were not taken at the time he had pericardial symptoms.

DR. WILLIAM BISHOP: I should like to comment about the head injury a year previously. I saw the patient outside the hospital for quite a long time because of that trouble, and had a chance to examine him repeatedly. I sent him to Dr. John S. Hodgson, with the question of whether he had residual hematoma following the head injury and fracture, but we could not make out that there were any definite signs. He had no good localizing evidence of any really organic cerebral damage, but it seemed to me as I observed him that he was slower mentally than originally, although he was never very brilliant, and it was difficult to be sure of that. He was asked whether or not he felt able to go to work. At times, he thought he could, and at other times that he could not; but he never did return to any occupation. His chief complaints up to the time of the last illness were headache and dizziness, dizziness especially on looking up too quickly. I saw him just before admission to the hospital, and the heart murmur, rales and especially the markedly bloody urine were the things that led me to urge him to come to the hospital. I was more or less jockeyed out of my impression that he had a heart murmur. Some heard it, and some did not. Then I changed my mind and said it was a systolic murmur. Now I should like to think I really heard a diastolic murmur. I knew that there must have been something abnormal in the heart that was giving rise to emboli, perhaps a mural thrombus. I did not come to a definite conclusion that he had bacterial endocarditis.

DR. FLETCHER H. COLBY: I saw the man mainly because of the hematuria. The gross hematuria in conjunction with the high nonprotein nitrogen and lack of excretion of dye in the intravenous pyelogram suggested some sort of nephritis. On the other hand, when I first saw him the nonprotein nitrogen was 50 or 60 mg per 100 cc, and we planned to cystoscope him to see if we could discover some source of bleeding, such as a bladder tumor. He quickly got too ill, and we canceled arrangements. That was the time of the embolus to the aortic artery. The spleen was easily felt when he first came in. That was not brought out in the history.

CLINICAL DIAGNOSES

Acute glomerulonephritis.
Uremia.

DR. RICHARDSON'S DIAGNOSES

Subacute bacterial endocarditis (alpha-hemolytic streptococcus), probably secondary to chronic rheumatic heart disease.
Embolic nephritis, with large renal infarcts.
Uremic pericarditis.
Cerebral embolus.
Multiple infarcts.

ANATOMICAL DIAGNOSES

Endocarditis, subacute bacterial, mitral.
Endocarditis, chronic rheumatic, mitral, with stenosis, and aortic, with interadherence of cusps.
Cardiac hypertrophy, moderate.
Pericarditis, serofibrinous, early.
Subacute glomerular nephritis.
Pulmonary hemorrhage, bilateral, interstitial, focal.
Splenic infarction.
Embolism of brachial artery, with extension into subcapsular artery.
Encephalomalacia, localized, bilateral, post-traumatic (head injury).
Hypertrophic pulmonary osteoarthropathy.

PATHOLOGICAL DISCUSSION

DR. MALLORY: Post-mortem examination showed bacterial vegetations on the mitral valve, superimposed on a well-marked calcareous rheumatic stenosis. There had been numerous emboli from this source. We located the one in the brachial artery, and found two small infarcts in the spleen and two in the kidney. The kidneys were very large, weighing 600 gm. The cortices were markedly swollen, and the surfaces were smooth but covered with petechial hemorrhages. There has been quite a little discussion of the question of embolic nephritis, and I think the clinicians today have used the term in a sense that is distinctly different from the usage of most pathologists. In the average case of bacterial endocarditis, one finds some changes in the glomeruli, and patients have during life, at least at times, hematuria. The ordinary case of bacterial endocarditis, however, shows these glomerular changes only in isolated glomeruli, whereas the majority of the glomeruli remain normal. Moreover, even an involved glomerulus may show inflammatory changes limited to only a portion of the tuft, the other loops of the tuft remaining perfectly normal. Consequently, most of the patients have good renal function, and a uremic death is rare. Because this type of glomeru-

lar disease occurs so regularly in bacterial endocarditis, it has often been called "embolic nephritis." There is really in most cases no direct evidence that it is embolic, and the same lesion is frequently found in acute disseminated lupus without endocarditis or other focus from which embolism could arise. Therefore, the term "focal glomerular nephritis" is preferable. I think what Dr. Richardson and Dr. Albright have been referring to is true demonstrable embolism to the kidney. This may be so massive, or miliary emboli may be so numerous, that renal insufficiency develops. Such cases are, however, rare. In this case, the microscopic sections showed a true diffuse glomerular nephritis indistinguishable from a primary glomerulonephritis. All glomeruli were involved more or less uniformly and completely, so that the development of renal insufficiency is not surprising.

There were one or two other findings of interest. The myocardium showed very obvious fibrous scarring in scattered spots throughout the heart. The aorta and coronary arteries, however, were practically free from sclerosis, and there was no evidence of any emboli to the coronary arteries. Later, on microscopic examination, it was apparent that these spots of fibrosis in the myocardium were all extremely old. There were no signs of any fresh myocardial necrosis, and no trace of inflammatory reaction in any of these scars. Consequently, this myocarditis must be put far into the past history, perhaps back to the time when the patient acquired the mitral stenosis, and hence may well have been of rheumatic origin. It is also conceivable that he had had diphtheria unknown to us in the past, which is the commonest source of that sort of lesion. The brain did show definite evidence of damage from the accident a year before. There were foci of superficial cortical atrophy, with marked hemosiderosis of the overlying arachnoid.

DR. HAMPTON: Sudden death was due to what?

DR. MALLORY: It was due to no cause that we could discover. There was massive acute pulmonary hemorrhage, or edema—very hemorrhagic serosanguineous fluid. The heart weighed 500 gm., and there was no atheroma of either the pulmonary or the coronary arteries.

CASE 28342

PRESENTATION OF CASE

A seventy-year-old man was admitted to the hospital because of persistent hematuria.

Three months before admission, the patient slipped while walking and twisted his right side. Following this, he had slight pain and an ache in the right flank that disappeared after several days.

At that time, he noticed the onset of hematuria, persistent to the day of admission except for a single period of three weeks. The degree of hematuria varied considerably and occurred during all parts of micturition. There was no dribbling, hesitancy or incontinence. A slight burning occasionally accompanied urination, and the patient occasionally suffered with nocturia and frequency.

Two months prior to admission, he was cystoscoped in the Out Patient Department and found to have a papillary growth of the bladder 1.5 cm. above the left ureteral orifice.

For three weeks before admission, the patient had an uncomfortable feeling in the left groin, and three days prior to entry he suffered with low midback pain lasting a day.

The past and family histories were irrelevant.

Physical examination revealed a well-preserved elderly man in no distress. Examination of the lungs and heart was negative except for a systolic murmur at the apex and over the aortic area. The abdomen was soft, and no masses were felt.

The blood pressure was 150 systolic, 92 diastolic. The temperature, pulse and respirations were normal.

The urine showed a +++ test for albumin, a few white blood cells and many red blood cells. There were no casts, and the concentration was good. A culture of the urine revealed a few colonies of *Staphylococcus albus*. Examination of the blood showed a red-cell count of 4,250,000 with 75 per cent hemoglobin, and a white-cell count of 6300 with a normal differential. The nonprotein nitrogen was 23 mg. per 100 cc., and the prothrombin was normal. The phenolsulfonephthalein test showed 35 per cent excretion in fifteen minutes, and an additional 15 per cent in half an hour. X-ray films of the skull and chest revealed no lesions resembling metastases.

Cystoscopy failed to reveal the papillary growth of the bladder previously seen in the Out Patient Department. An intravenous pyelogram showed delayed excretion of the dye, which faintly outlined the ureters and kidneys. The bladder outline was relatively smooth; there was a slight defect at the base consistent with an enlarged prostate. A retrograde pyelogram demonstrated bilateral pressure defects along the upper surfaces of both kidneys. However, the lower poles were relatively normal.

Operation was performed on the fourth day after admission.

DIFFERENTIAL DIAGNOSIS

DR. GEORGE G. SMITH: The question in this case is whether a twist of the torso sustained while the patient was walking, without any actual fall, could cause bleeding from trauma of a normal kidney.

I do not believe it would. I think it might if the patient had renal stone or hydronephrosis or some pathologic condition in the kidney, which might be ripped or torn by any unusual motion.

The fact that the bleeding occurred during all parts of micturition is rather against a prostatic origin. Usually, blood from the prostate precedes urination—not always, but usually. Furthermore, there was no dribbling, hesitancy or incontinence, and nothing to substantiate a diagnosis of prostatic bleeding.

The answers to two questions would be helpful. Did the patient have any bladder residuum? Was the blood seen coming from the ureter or any particular source at the time of cystoscopy?

DR. TRACY B. MALLORY: Can you answer either of those two questions, Dr. Gens?

DR. JOHN P. GENS: There was no bladder residuum, and no blood could be seen coming from either ureter at the time of cystoscopy.

DR. SMITH: Was the patient bleeding at the time?

DR. GENS: No.

DR. SMITH: It is a good thing to cystoscope patients with hematuria at the time there is blood in the urine, because then one can get an indication of the origin of the blood, which one often cannot get later on.

The fact that cystoscopy failed to reveal the papillary growth probably means that the alleged papilloma was a blood clot adherent to the bladder wall. It is very difficult to distinguish between an adherent blood clot and a papilloma that has been bleeding and is infiltrated with blood. With kidneys that show as good a renal function by non-protein nitrogen and phenolsulfonephthalein tests as this man's kidneys did, one expects to see a very good picture of the kidney pelvis from the Diodrast or Neoskiodan, whichever one was used, unless he was not well prepared and had a great deal of fluid.

From the story to date, I have not the slightest idea what this man was operated on for. May we see the x-ray films?

DR. LAURENCE L. ROBBINS: These are the films of the intravenous pyelograms, and as noted, there is no good visualization of the calyces, pelves or ureters. The retrograde pyelogram, in contrast, shows these very obvious bilateral pressure defects in the outlines of both pelves. They are nearly symmetrical, but there is more involvement of the superior calyx on the left.

DR. SMITH: They are excellent and unusual films, I should say. The simultaneous bilateral occurrence of tumor is possible, but very unusual. It is much more likely that the patient had bilateral solitary cysts. The pelves and calyces do not give the picture of congenital polycystic kid-

neys. Furthermore, the renal-function tests are too good for a case of polycystic kidneys in a man of this age. On the other hand, there is very definite pressure here, as Dr. Robbins has pointed out. The uppermost calyx is thinned out over a presumably smooth, symmetrical round tumor. It is quite possible to get marked hematuria from solitary cyst of the kidney, perhaps owing to interference with the blood supply, sometimes with rupture of the cyst. I should make a diagnosis of bilateral solitary cysts of the kidneys. I do not know which side I should operate on or why, but that is my diagnosis.

DR. MALLORY: Would you have operated on this patient on this evidence?

DR. SMITH: I suppose he could have had a tumor on one side and a cyst on the other, but it would be unusual to have the findings so symmetrical. If he had had successive episodes of bleeding and if observation had shown that he always bled from one side, I should be inclined to operate on that side. If it were a tumor, I should take out that kidney, and if it were, as seems more probable, a solitary cyst, I believe that removal of such a cyst would check the hemorrhage and that it would be to the patient's advantage to operate.

DR. WILLIAM B. BREED: Without that evidence, where would you operate?

DR. SMITH: As I say, I should want to know from which side the bleeding was coming. We do not know that from the history.

DR. BREED: Well, where are you going to operate—midline, right or left?

DR. SMITH: I should guess that the left kidney would be the one to pick because the upper calyx appears to be more involved in the x-ray film than the one on the other side, but I do not believe that is sufficient reason for selecting that side. I should insist on knowing which side was bleeding, and if this elderly man stopped bleeding and had no symptoms, I should leave him alone.

DR. J. DELLINGER BARNEY: What about bilateral adrenal tumors?

DR. SMITH: These lesions very evidently involved the structure of the kidney itself—the parenchyma of the kidney. So far as I know, adrenal tumors do not do that; they push the kidneys down but do not invade them.

DR. FLETCHER H. COLBY: It would add to the interest of the discussion if Dr. Smith were told the next step.

DR. MALLORY: We are prepared to do that. Dr. Gens, will you proceed?

DR. GENS: We never did know from which side the bleeding was coming. When the patient was admitted to the hospital, the gross hematuria stopped. The urine on both sides showed red blood cells. We decided to operate on the right

side because we believed that the chance of cyst was greater on the left side since the calyces were actually involved on the left side, whereas the tumor was pushing the pelvis or the calyx away on the right side, which would be more like neoplasm. Therefore, we operated on the right, came down on a cyst and treated it in the usual fashion.

DR. MALLORY: Would you then wish to do anything more, Dr. Smith?

DR. SMITH: I should assume that there was a cyst on the other side also, and unless he bled again or had further symptoms, I do not believe I should operate.

CLINICAL DIAGNOSIS

Cortical cysts of kidneys.

DR. SMITH'S DIAGNOSIS

Bilateral solitary cysts of kidneys.

ANATOMICAL DIAGNOSES

Solitary cyst of right kidney.

Papillary adenocarcinoma of left kidney.

PATHOLOGICAL DISCUSSION

DR. MALLORY: Suppose you go ahead with the story, Dr. Gens.

DR. GENS: About seven days later, although the patient had a perfectly uneventful immediate postoperative course, he once more had gross blood in the urine.

DR. SMITH: May I ask what you did to the right kidney?

DR. GENS: We excised the wall of the cyst. Then we decided to aspirate the left side but did not obtain anything but a few drops of blood, although we were fairly certain that we had touched the tumor mass in the left kidney.

DR. SMITH: But you knew the blood was coming from the left side?

DR. GENS: No.

DR. SMITH: I believe I should have looked in the bladder to see if the blood were coming from the left side.

DR. MALLORY: I think by exclusion it was believed that the hemorrhage must have been coming from the other side.

DR. SMITH: I think that is assuming too much; however, it probably was so. But I do not believe one can take anything that is easily demonstrated for granted. One could easily put in a small cystoscope and look at the ureters.

DR. MALLORY: Eventually, the patient was explored on the left side, an obvious tumor was found, and a nephrectomy performed. He made an uneventful convalescence. The tumor proved to be a papillary adenocarcinoma of renal origin.

THE SPREAD OF INFANTILE PARALYSIS

It is difficult to correlate the fact that the incidence of infections of the upper respiratory tract is lowest and that of poliomyelitis—a disease in which the upper respiratory tract is generally considered to be the important, if not the only, portal of entry of the virus of infantile paralysis—highest during the late summer and early fall. This view concerning the origin of poliomyelitic infection has been based chiefly on the following facts: the virus of poliomyelitis has been demonstrated in nasal washings obtained in the early stages of the infection, the disease, during out-

breaks, is considered to occur with more than the expected frequency in relation to tonsillectomy, and it is relatively easy to infect the susceptible monkey with the virus by intranasal inoculation.

Recent experimental work, however, indicates that the nasal passages may constitute a point of exit as well as of entrance for the virus of poliomyelitis. Thus, the virus has been recovered from the nasal secretions of monkeys infected by inoculation into the brain and even into the peritoneum. Furthermore, in monkeys inoculated intranasally, the virus disappears from the nose a few hours later and reappears there after a lapse of about forty-eight hours.

Increasing evidence is being brought forth to implicate the gastrointestinal tract as the route of infection in poliomyelitis. This, of course, is much more consistent with the seasonal incidence of the infection, and the long known association of epidemics of the disease with the course of rivers and in relation to other bodies of water. Even as early as 1912, Kling and his colleagues,¹ in Sweden, reported the finding of the virus of infantile paralysis in the stools of human cases. This observation has been confirmed and extended sporadically by a number of workers, but intensive investigations based on this finding have been carried out only during the last three or four years.

Briefly, it has now become clear that the virus of poliomyelitis can be demonstrated quite readily in the stools of frank cases and of so-called "abortive cases." In fact, the virus can be found much more frequently and over much longer periods in the stools than in the nasal passages. The specific virus has also been identified in the stools of a large percentage of intimate, but healthy, contacts of cases, as well as in the sewage from homes and areas where the disease is prevalent. Furthermore, it has been shown to exist in the stools of patients and carriers for considerable periods. These findings have recently been reviewed by Armstrong² and by Paul.³

The ease of identifying the virus of poliomyelitis in stools has proved to be of the greatest help in epidemiologic studies of this disease. Re-

cently, Piszczek, Shaughnessy, Zichis and Levinson⁴ reported the results of their studies of an outbreak in a suburban community in Cook County, Illinois. The outbreak involved 15 cases between June 4 and July 11, 1941. In 3 out of 4 patients, the virus of poliomyelitis was demonstrated in samples of feces collected about one month after the onset of symptoms. The virus was also found in the stools of at least 8 out of 48 contacts, but not in the feces of 25 healthy residents of the same community who had had no contact with the disease. In view of previous epidemiologic notions concerning the familial spread of the disease, it is noteworthy that the virus was found in the stools of 2 presumably healthy children who were in contact with adult members of their families who, in turn, became ill with poliomyelitis. The authors succeeded in isolating the virus from a supposedly healthy carrier two months after he had had contact with persons who became ill with poliomyelitis and one month after exposure to his father, who died of poliomyelitis.

The epidemiologic evidence brought to light by these studies seems to point strongly to a spread of the disease by apparently healthy carriers—a view that has been held for over twenty-five years by the Swedish workers, who supported the contention that the infection was spread by way of the gastrointestinal route.

All these findings are beginning to clarify the picture of the epidemiology of infantile paralysis. It is hoped that they will result in the development of effective measures for the control of this disease.

DRUGS AND MENTAL DISEASE

It is encouraging that drugs and chemical agents are very minor causes of mental disease in Massachusetts: a recent study¹ indicates that of 115,000 patients cared for in Massachusetts mental hospitals between 1917 and 1937, only 841 cases seemed to have been associated with the use of drugs and chemicals. Of these, 36 cases were unverified, so that the actual number was 805 cases, or less than 0.7 per cent. These cases were diagnosed as "psychoses due to drugs and other exogenous toxins," except for cases labeled "without psychosis: drug addiction."

A comparison of these cases with those related to alcoholism originating in the same geographic area during the same period is interesting. According to Dayton,² alcoholism caused more than fifteen times as many entries to state mental hospitals as drugs. Furthermore, many of the patients using drugs also drank alcohol in excessive amounts and therefore might have been classified as alcoholic cases with equal validity: among first admissions related to drugs and chemical agents, 50.4 per cent of men and 25.5 per cent of women were intemperate users of alcohol, and Dayton found that 32.0 per cent of all men admitted with psychoses and 6.0 per cent of all women were intemperate.

It appears that users of drugs are not especially selective in their choice of pharmacologic comforts, since these patients took more than one drug (sometimes three or four) either concurrently or successively.

Many persons in the group stated that their use of drugs began when they were given drugs on prescription by a physician. They may have had the prescription refilled, or the physician may have failed to withdraw the drug when the specific need was over. A few began taking drugs on the advice of friends or relatives, but self-medication was a less important factor than therapeutic use under medical advice. Despite the limited number of cases represented, physicians should be aware of the possibilities that may follow the injudicious use of drugs.

Perhaps the most striking finding in the study, aside from the excessive use of alcohol, was the high incidence of abnormal personality traits and prepsychotic personalities. Many patients had histories of frank mental disease and previous admissions to mental hospitals for reasons unrelated to drugs. It might be assumed that their resort to drugs was a symptom of psychologic illness and that the intoxication or addiction was a result rather than the cause of illness.

The major drugs reported were as follows: opium and its derivatives, 363 cases; barbiturates, 208 cases; and bromides, 101 cases. Many of the cases were suicidal, accidental or due to industrial exposure and cannot be considered in relation to addiction — the standard classification groups cases of this type with all others related to chemical agents.

Among the facts emphasized in this study is the need for the physician to recognize the limitations of medication related to mental disease and to be especially aware that the uncontrolled use of certain drugs may precipitate mental disease in patients who are predisposed, who have histories of previous mental illness or who are inclined to have unstable personality trends. The need for additional investigation into the effect of drugs on personality is evident.

In addition, it is pointed out that the complications of drug addiction may be related to the faulty diets, the avitaminoses and the abnormal regimes of personal hygiene of drug users, as has been shown for alcoholic complications. The heterotropic quality of the addiction pattern in this group is of interest because it seems to demonstrate that one drug can be substituted for another and that, consequently, little additional evidence is needed to demonstrate conclusively that addiction is more basically associated with personality types than with specific chemical agents.

MEDICAL EPONYM

RAUCHFUSS'S TRIANGLE

Although Carl Rauchfuss (1835-1915) discussed "Die paravertebrale Dämpfung auf der gesunden Brustseite bei Pleuraergüssen (The Paravertebral Dullness on the Healthy Side in Pleural Effusions)" before the Pediatric Society of St. Petersburg in April, 1903, the first published account of his finding appears under the above title in *Verhandlungen der Einundzwanzigsten Versammlung der Gesellschaft für Kinderheilkunde in der Abteilung für Kinderheilkunde der 76. Versammlung der Gesellschaft deutscher Naturforscher und Ärzte in Breslau, 1904* (21:202-211, 1905). A portion of the translation follows:

The clinical finding . . . is the triangular area of dullness, which can always be demonstrated by percussion or palpatory percussion, on the healthy side, along the vertebral column and extending upward to a height that depends on the extent of the pleural effusion, frequently as high as its upper level. The base of the triangle corresponds to the lower border of the lung, and its hypotenuse leaves the base at a distance of 2 to 5 cm. from the spinous processes (in childhood).

COMMITTEE ON MATERNAL WELFARE

CASE HISTORY: POST-PARTUM SHOCK FOLLOWED BY DEATH

A twenty-eight-year-old primipara had had adequate prenatal care. The past history was irrelevant, and at no time during her pregnancy was elevation of the blood pressure or albuminuria noted. There had been no flowing, and the size of the pelvis was adequate. Labor started spontaneously and lasted twenty-six hours until full dilatation. Delivery was difficult because of a transverse arrest, but a living child was obtained. Immediately after delivery, the patient went into shock, the pulse rising to 160 (the blood pressure was not recorded). Extraction of the placenta offered no problem, and there was no unusual bleeding. Eight hours after delivery, the hospital authorities thought the patient to be in such poor shape that they took it on themselves to call an obstetric consultant, who stated that her condition was critical. Although there was no alarming bleeding at this time, she was in profound shock, presenting such typical signs as cold, clammy skin, rapid, weak pulse and low blood pressure. The consultant advised immediate transfusion, but this measure was not carried out at once because the patient's physician saw her soon afterward and

After a year's work in the poorly equipped laboratory, during which he had demonstrated to the profession the wide range of usefulness of the x-ray, Dr. Williams felt the necessity of the services of a professional photographer and mechanic and secured Ernest E. Fewkes, who had done much original work along these lines. The trustees of the Boston City Hospital later appointed Mr. Fewkes to the position of photographer and x-ray assistant to the hospital. That was June 18, 1893, only three years after the discovery of the x-ray. Mr. Fewkes's ability as a photographer, mechanic and all-round scientist enabled Dr. Williams to make great strides in his research work.

Mr. Fewkes received many x-ray burns while working with this light in the days before anything was known of the danger in being exposed to the rays. One by one, he lost three fingers on each hand as the result of burns sustained forty years ago. Later, internal burns developed, which finally resulted in death, which occurred at his home on Hyde Street, Newton Highlands, on July 16.

NOTES

The Massachusetts Society for Mental Hygiene announces the resignation of its medical director, Dr. Henry B. Elkind, effective August 12, when he entered active service as a major in the Medical Corps of the United States Army. Dr. Elkind had served as medical director of the society since 1925, and his able administration brought recognition of the society's leadership in the field of mental-hygiene education, not only in Massachusetts but throughout the Nation. During his directorship, which was characterized by resourcefulness, vision, and energy, he did much to extend the application of mental-hygiene principles to many important fields of community life, including child care, industry, social work, public-school education and teacher training. One particular branch in which he achieved special success is the application of statistics to the study of mental disease, and he is recognized as one of the foremost leaders in the country in the epidemiology of mental disease. Under Dr. Elkind's direction, the Massachusetts Society for Mental Hygiene has adapted its program to meet wartime needs, and he leaves it in a strong position to continue its contribution to the welfare of the community under the changed and difficult conditions of today.

Dr. Frank H. Washburn, of Holden, was recently elected governor of the American College of Chest Physicians at the annual meeting of the college. Dr. Richard H. Overholt, of Brookline, was elected second vice-president.

CORRESPONDENCE

A CORRECTION

To the Editor: It has come to my attention that you have reprinted my article "Unsocialized Medicine," in a special supplement to your journal. I was pleased to have my dissenting remarks included among the newspaper pieces lauding the new prepayment plan of the Massachusetts Medical Society, and was impressed by the profession's tolerance of my somewhat sharp criticisms.

However, you erred in identifying me as "president of the White Cross," and I'd appreciate your correcting this so as not to expose the White Cross (which supported the Massachusetts Medical Society legislation) to professional criticism for my personal views.

Francis H. Russell, now with the State Department in Washington, is president. Edward A. Taft, vice-president

and Boston lawyer, has been acting president during his absence. I functioned only as president of the unofficial but enthusiastic Association of White Cross Members.

HAROLD PUTNAM

The Boston Globe
Boston

* * *

The *Journal* acknowledges its error of referring to Mr. Putnam as president of the White Cross. Incidentally, it is pleased to learn that the views of Mr. Putnam are purely those of an individual and not those of an organization—either the White Cross or the Association of White Cross Members. Ed.

REPORT OF MEETING

BOSTON LYING-IN HOSPITAL JOURNAL CLUB

At a regular meeting of the Boston Lying-in Hospital Journal Club, held at the hospital on April 15, Dr. Edwin H. Place discussed "Contagious Disease in Relation to Obstetrics."

Although this is not a common problem, it becomes important in the individual case so far as care is concerned. There have been only 76 cases of communicable disease during pregnancy or immediately post partum in 50,000 admissions studied at the South Department of the Boston City Hospital. There were 8 deaths, but 4 of these occurred in cases of scarlet fever before the use of sulfonamide compounds, and this is still a serious problem. The task of prevention seems impractical; however, nearly all cases are preventable. It is no longer necessary for the obstetrician to refrain from treating streptococcal cases with the present knowledge of bacteriology and asepsis; but a physician assumes a grave responsibility if he treats these patients when such diseases can be avoided.

If the question arises of admitting for delivery a woman of a family in which scarlet fever has occurred very recently, the finding of a negative Dick test and negative cultures makes her safer than a routine admission. However, routine cultures are impractical because of the lack of knowledge of when or over how long a period prior to confinement they should be carried out. If cultures are contemplated, the staff should be periodically tested, for completeness. The finding of a few streptococcal or diphtheritic carriers in this manner is inconsequential when one considers the many that are missed. If such a program of safety is contemplated, it is better to immunize the carriers so that they will do no harm. On the whole, however, Dr. Place suggests that carriers be ignored, for they cannot be adequately treated and it becomes a burden to isolate them for weeks or months. He believes that pregnant women should be immunized, but most of the urban population is immune anyhow. In diphtheria, the prospective mother alone can be freed of suspicion by culture and Schick test.

If there has been mumps in the home, the woman in urban life will undoubtedly be immune, and if not, the opportunity for spread is remote. There are no good tests in this disease, and one can only rely on these probabilities. The giving of convalescent serum during the incubation period is sound. In chicken pox, the chances that an adult will contract the disease, even if exposed, are small. Measles is of little practical significance, since the children of urban mothers are usually immune.

In general, it has become the accepted policy of large

urban maternity hospitals not to admit any suspicious cases, and such women must be delivered at home under proper precautions or in a hospital for contagious diseases.

The incidence of communicable disease in the newborn is rare, especially those contracted in utero. Measles, smallpox and chicken pox are known to be contracted thus. Only one infant at the South Department of the Boston City Hospital has developed scarlet fever, and the children are always kept with their mothers. On the whole, this disease is rare under one year. Diphtheria is possible but at present unusual.

In discussing some slides, Dr Place made several practical suggestions. Vaccination should never be carried out in the presence of eczema because of the danger of generalized vaccinia. Chicken pox is not contagious when the exanthem is pigmented. When this disease occurs during scarlet fever, all the lesions arrive at once, pass through the stages simultaneously and rapidly, and have the distribution of scarlet fever. The most valuable differentiation of smallpox and chicken pox is the rapidity of the changes in the former in contrast to even slight cases of the latter.

The discussion was opened by Dr Stewart Clifford, who advocated specific admission rules for all outpatient departments. Dr Arthur Hertig presented the case of a four and a half months' fetus with smallpox. He suggested that viruses may cross the placental barrier where as bacteria do not, in general.

In conclusion, Dr Place emphasized the rarity of in utero infections of this type. The question of whether coryza in an adult is actually a minimal whooping-cough infection may be settled by the proper use of cough plates and the finding of lymphocytosis. He believes that the benefit of convalescent serum is overemphasized. There is no center for this in Boston at present. So far as in utero immunity is concerned, it has been proved that the organisms of at least diphtheria, scarlet fever, whooping cough and mumps may pass across the placental barrier and, possibly, may even be concentrated thereby. But urban mothers are invariably immune to these organisms.

He made the following suggestions in answer to Dr Clifford's request for specific outpatient department rules. In diseases in which susceptibility tests are available, these may be carried out prior to confinement when time allows it. In cases of exposure to measles, chicken pox and mumps in the nonimmune mother, convalescent serum is not trustworthy enough to make admission more than a gamble. Such women probably should not be admitted if delivery is expected during the incubation period. If it becomes necessary to admit them, isolation is advised, and not much harm can ensue at worst.

BOOK REVIEWS

Surgery of the Heart By E S J King, M.D., M.S., D.Sc. (Melb.), FRCS (Eng.), FRACS, Major A.A.M.C. 8", cloth, 728 pp., with 4 plates and 268 illustrations. Baltimore: Williams and Wilkins Company, 1941. \$13.50.

This first monograph of any size in the English language on surgery of the heart was written by a thoracic surgeon of Australia. It gives a wide survey of practically all surgical procedures that have been performed, or even

suggested, on the heart and great vessels. In fact, the chief difficulty the reviewer finds with the book is that it is too expansive and includes a good deal of irrelevant matter concerned with medical rather than surgical aspects of heart disease. The volume could profitably be shortened by the omission of much of the material, which can be found in more detail in other books on cardiac physiology and disease.

The work is divided into two sections. The first takes up the anatomy, histology, physiology, embryology and pathology of the heart, with a discussion of roentgenology and electrocardiography. It is this part of the book particularly that might have been omitted or radically shortened to advantage. The second section deals in its introduction with the surgical approach to heart disease and with experimental investigations, and then considers, in order, the various diseases of the myocardium, endocardium, pericardium and great vessels. Of most practical value are the discussions of the treatment of cardiac wounds, foreign bodies and pericardial disease. There is a tendency to overstress surgical relief for myocardial and coronary heart disease, considering their relative unimportance or lack of success. It still remains to be proved how much good can be done for coronary heart disease by any surgical measures, too often, the common tendency for states of coronary insufficiency to correct themselves, no matter what therapy is carried out, is not recognized. There is an inadequate account of the important new operation introduced by Gross and Hubbard, of Boston, for closure of the patent ductus arteriosus.

The book is well arranged, and the frequent historical notes are of especial interest. An ample bibliography is appended to each of the section subdivisions, and should be very helpful for reference. There are numerous illustrations, a few of them in colors; many are helpful in relation to the subject at hand, but a considerable number might usefully have been omitted from a volume with this title. The book is attractively printed and bound.

Nostradamus: The man who saw through time By Lee McCann. 8", cloth, 421 pp. New York: Creative Age Press, Incorporated, 1941. \$2.75.

In the last few months, there has been a revival of interest in Nostradamus, or at any rate in the prophecies of Nostradamus, which relate to certain world events up to 1999. There are those who pretend to discern, in the forecasts of this sixteenth-century astrologer, specific references to the humiliation of France, to Adolf Hitler and even to Pearl Harbor, although the attack had not occurred when this book went to press. Let those who believe take comfort, after these dark hours, the Axis powers are doomed to defeat. But it will not do to relax, merely on these prophetic grounds.

Two thirds of this book is devoted to a fictionalized biography of Nostradamus, and of the last portion to the predictions themselves, with elucidations of the particular modern events to which they refer. They need elucidation, for they are as obscure as the Apocalypse. But perhaps we have not the requisite faith. Miss McCann has, she is a hero-worshiper, at least of Nostradamus, whose life—he was a successful medical practitioner long before his ventures into world prophecy came to absorb all his energies—is painted as if he were one of the great. Some of us would be more inclined to rank him with Cagliostro or Elisha Perkins.

Symptoms in Diagnosis. By Jonathan C. Meakins, M.D., LL.D. 8°, cloth, 323 pp., with 54 illustrations. Boston: Little, Brown and Company, 1941. \$4.00.

The importance of symptoms in diagnosis is well attested by this book, which is not a text of clinical medicine but rather a survey of symptoms as related to various syndromes and pathologic entities. It is written in a fascinating style, and its readability is enhanced by the elimination of all bibliographic references. Only a master of his field, as Dr. Meakins has proved himself to be, can assume this prerogative.

Dr. Meakins writes: "[The study of symptoms—as part of clinical medicine—] . . . needs young minds untrammelled by superstition and preconceived and fixed ideas which are the most deadly of all impediments to the advancement of medical knowledge. But with all this, there is a wonderful hope that through harnessing exact science in the way of sterol and physical chemistry and their sisters, electrophysics and biophysics, the day is not far hence when this tangle will be unsnarled and there will be gleams of light to illuminate the pathway to truth and understanding."

The pleasure of reading this work is akin to that which the bibliophile derives from browsing among books. Students and practitioners will find this volume particularly valuable.

Diseases of the Blood and Atlas of Hematology: With clinical and hematologic descriptions of the blood diseases, including a section on technic and terminology. By Roy R. Kracke, M.D. Second edition, thoroughly revised, reset and enlarged. 4°, cloth, 692 pp., with 54 color plates and 46 other illustrations. Philadelphia: J. B. Lippincott Company, 1941. \$15.00.

That a second edition of Kracke's large and expensive book is forthcoming within a few years indicates its recognition as a standard text. The reviewer must confess, however, to a certain disappointment, which is perhaps based on his own idiosyncrasies regarding hematologic exposition. These derive from two fundamental and related concepts: that the hematologist is no longer a pathologist, but a clinician with a knowledge of the laboratory, and that hematology has advanced a long way from its previous preoccupation with the blood cells as the be-all and end-all of the subject. Hematology is now internal medicine, physiology and physiologic pathology, biochemistry and pathology. For these reasons, a work by a pathologist, however broad his outlook, must have its shortcomings, which indeed this volume possesses. Fully a third of the volume deals with variations in the morphology of the blood cells, with the result that the physiologic pathology and clinical features of some conditions are often not sufficiently stressed. There seems to be much absorption with systematization, terminology and classification, which savors of the ponderous Teutonic texts, formerly so popular. On the other hand, the pictures of blood smears and cells far outrank anything else in this country and for the *Atlas* alone, the book is worth owning. The lithography is unusually good.

There are excellent sections on agranulocytosis, in which the author did some of the pioneer work, and on leukemia. In the description of such preponderantly clinical conditions as pernicious anemia, idiopathic hypochromic anemia and the hemolytic anemias, however, the discussion is often pedantic, immersed in too many quotations from various authors and impeded by too much classification. For example, hemolytic anemia is discussed separately from hemolytic jaundice, although physiologically they are related conditions. The statement that the fragility of the

red cells is always normal in acquired hemolytic anemia does not agree with numerous recent observations. Perhaps because the author is primarily a pathologist, considerations of therapy are often not only scant but misleading. This holds true not only for the treatment of acquired hemolytic jaundice, in which splenectomy is brushed aside as having little or no value, but also in the management of an acute case of idiopathic thrombopenic purpura. The statement is made that "splenectomy should not be attempted in the patient who has the disease in the acute form with severe hemorrhages, nor should it be done in those who are in a bleeding episode even though the course has been chronic." Unfortunately, many a patient has been lost—usually through cerebral hemorrhage—while physicians have been debating and temporizing. It is particularly in the acute form that splenectomy must frequently be done as an emergency measure. With a good surgeon, the risk is slight, and far less than that involved in temporizing.

The descriptions of thrombopenic purpura, polycythemia and Cooley's anemia are scant, and there is only a short paragraph on erythroblastosis foetalis. There is no discussion of the recently much discussed entity of leukoerythroblastic anemia associated with ectopic myeloid metaplasia. However, von Jaksch anemia, which has been regarded as defunct, rates a large paragraph. On the other hand, Custer's section on the bone marrow is good, as is the one on malaria and on hematologic technic.

In general, this is a good one-volume text on hematology, excellent for its histologic descriptions and pictures, but lacking somewhat in physiologic and clinical feeling. The printing and format are excellent, and the index and bibliography are good.

Eye Hazards in Industry: Extent, cause and means of prevention. By Louis Resnick. 8°, cloth, 321 pp., with 33 illustrations, 13 tables and 2 charts. New York: published for the National Society for The Prevention of Blindness by Columbia University Press, 1941. \$3.50.

For the guidance of safety engineers, industrialists, workers and the medical profession in the prevention of eye injuries in industry comes this third volume in the past twenty-five years, published for the National Society for the Prevention of Blindness, and posthumously by the author Louis Resnick, who records his two decades of first-hand contacts with factories, mills and mines in the conservation of vision.

The first portion of the book deals with the problem of ocular hazards in industry, with especial reference to accidents, diseases of the eyes and defective vision. Each year in this country 300,000 workmen suffer eye injuries costing employers and employees the total of \$200,000,000, 98 per cent of which are preventable. The author estimates that 80,000 workmen in this country have lost one eye and that 8000 workmen have lost both eyes as a result of preventable injury.

The second portion of the book deals with the solution of the problem through safety design, mechanical guards and reduced hazard at the machine; through safety devices to shield the eye; through adequate illumination; and through education of the workmen in the proper use of the appliances.

All statements are well supported by statistical evidence, and the book carries four appendices that contain useful information about industrial poisons hazardous to the eyes, minimum standards of illumination, and industrial welfare organizations.

ERYTHEMA NODOSUM*

M. H. POPPEL, M.D.,† and A. M. MELAMED, M.D.‡

NEW YORK CITY

DURING the years 1928-1941, 88 patients were discharged from the Mount Sinai Hospital, New York City, with a diagnosis of erythema nodosum. These cases were reviewed from two standpoints to analyze the clinical data from the point of view of associated diseases, and to determine whether any specificity to the mediastinal or hilar adenopathy, or both, is shown roentgenologically.

ETIOLOGY AND INCIDENCE

The etiology of erythema nodosum, a doubtful tuberculide, is not known. Originally, it was believed to be an acute specific febrile and mildly communicable disease. Accumulating evidence (Spink,¹ and Paul and Pohle²) suggests that it is not a specific pathologic entity but a nonspecific toxic complex with many precipitating or provoking factors. It may occur during the course of various conditions, both infectious and non-infectious.

It is three to five times more prevalent in females and most frequent in young persons. It is rare in children under the age of three and in very old people. It is most prevalent during the spring season. The incidence of erythema nodosum, as well as the type of disease it is associated with, varies with the habitat, type and age of the patients, according to other series reported in the literature.

Wallgren³ has shown that in Scandinavian children 95 per cent of the cases of erythema nodosum appear with tuberculosis, in England, this percentage is 70, and in this country it is lower. He believes that in tuberculous children the erythema nodosum appears when the child becomes tuberculin sensitive.

In adults, less emphasis has been placed on

tuberculosis as an etiologic factor and more on rheumatic fever and streptococcal infections (Paul and Pohle²). Keil,⁴ after a critical study of the subject, believes that erythema nodosum is not of rheumatic origin.

Dickson⁵ has called attention to the association of erythema nodosum and coccidioidomycosis as seen in the San Joaquin Valley, where the latter is known as "valley fever" or "desert fever."

PATHOLOGY

Grossly, the lesions of erythema nodosum consist of discrete, firm, hot, tender conical elevated nodules about 1 to 5 cm. in diameter and symmetrically distributed. The lesions appear most frequently over the anterior aspects of the legs and less frequently over the forearms, arms, thighs, buttocks and face. The average case shows about eight to ten nodules, which have a glossy surface and vary from a bright red to a deep purple. As the nodules begin to regress, they undergo the color involutions of a bruise or contusion.

Histologically, these erythematous nodules suggest nonspecific inflammation. Ormsby⁶ describes the changes as "vascular dilatation, marked edema of the collagen, small round-cell infiltration, largely perivascularly arranged in the middle and lower portions of the corium and to a lesser extent in the papillary and subpapillary portions." He also points out that epidermal changes are usually absent.

ANALYSIS OF CASES

This analysis is based on a clinical diagnosis of erythema nodosum made on discharge from the hospital. The patients did not come under our personal clinical observation. In this series of 88 cases, the condition was three times more prevalent in females, and the ages of the patients ranged from two to fifty-eight years (Table 1).

‡Formerly resident in radiology, Mount Sinai Hospital.

Associated Diseases

Many diseases and conditions were found to be associated with erythema nodosum. Often, two or more conditions or complaints occurred in the

TABLE 1. *Age and Sex Distribution in 88 Cases of Erythema Nodosum.*

Totals	66	22	88

same patient, either preceding or during an attack.

In 13 cases, no evidence of associated disease was present. The remaining 75 cases were found to be associated with the following conditions.

Tuberculosis. Four cases were associated with tuberculosis.

The first patient, a five-year-old boy, entered the hospital on November 17, 1928, with two soft-tissue masses, one in the region of the elbow and the other in the region of the ankle. Tubercle bacilli were recovered from the aspirated contents of the soft-tissue masses. Enlargement of the cervical, axillary, epitrochlear, inguinal and submaxillary lymph nodes was found. There was no pulmonary infiltration or mediastinal or hilar adenopathy in the chest roentgenograms. The patient died fourteen months later as the result of tuberculous meningitis.

The second patient, a six-year-old boy (Case 11, Table 2), had enlargement of the mediastinal and hilar nodes on the first roentgenogram of the chest. Eighteen days later, the chest was re-examined and showed, in addition to the previous findings, widespread nodular pulmonary infiltrations bilaterally. The tuberculin test was strongly positive. Autopsy performed at another hospital eight months later showed hematogenous miliary tuberculosis involving the lungs, meninges and practically all the other viscera. The mediastinal and hilar lymph nodes were involved by caseous tuberculosis.

The third patient (Case 7, Table 2), a nine-year-old boy, showed a pneumonic infiltration extending from the left root to the periphery of the left upper lobe and enlarged hilar nodes. The tuberculin test was strongly positive. Physical examination revealed enlargement of the cervical and epitrochlear lymph nodes. The clinical discharge diagnosis was childhood pulmonary tuberculosis. The patient failed to report for follow-up studies.

The fourth patient (Case 14, Table 2), a thirty-four-year-old woman, had been under observation in the Out Patient Department for the previous ten years. A tuberculin test performed seventeen days after the onset of erythema nodosum yielded a strongly positive local reaction, with generalized symptoms of malaise, fever and so forth. Seventeen days later, or thirty-four days after the appearance of the erythematous nodules, one of the lesions on the right leg ulcerated. Biopsy of one of the lesions on this leg showed the changes of erythema nodosum. A roentgenogram of the chest revealed numerous fibrocalcified areas in both upper lobes. Calcifications in the cervical nodes were also seen on the left side of the neck. There was no evidence of recent pulmonary infiltration or consolidation, and guinea-pig inoculation of the gastric contents revealed no evidence of tuberculosis. Within several months, three additional crops of erythematous nodules appeared. The chest roentgenogram remained the same.

Rheumatic heart disease. Of the 7 patients with definite rheumatic heart disease, 2 developed the erythematous lesions while in the hospital during episodes of cardiac decompensation.

There were 10 additional patients with questionable rheumatic heart disease. In 1, in whom rheumatic nodules developed on the ninth and twenty-first days of hospitalization, there was no evidence of heart disease. In the region of the elbows, the nodules of erythema nodosum and the rheumatic nodules were present simultaneously, but were easily differentiated clinically. When this patient returned for follow-up study two years later, there was still no evidence of heart involvement.

Chest roentgenograms were taken in 6 of the 7 cases associated with definite rheumatic heart disease, and in none of these were there any intrathoracic abnormalities, such as enlarged nodes and pulmonary infiltration.

Upper respiratory infection. Most of the 49 cases in this group were associated with upper respiratory infections of streptococcal origin. This group included cases of so-called "grippe," pharyngitis, tonsillitis, sinusitis, peritonsillar abscess and bronchitis. The majority of these patients entered the hospital with a history of illness lasting from a few days to about two weeks. Half showed evidence of peripheral lymphadenopathy. Chest roentgenograms were made in 34 cases of this group, and in 11 there was evidence of enlarged mediastinal or hilar nodes. Clinically, 5 patients of the latter group also had enlargement of the cervical nodes.

Arthralgias. In erythema nodosum, the complaint of joint pain or arthralgia is difficult to evaluate. One must attempt, and often one is unable, to differentiate a true joint pain from pain that is secondary to the inflammatory changes brought about by the erythematous lesions, particularly when the lesions occur in the vicinity of joints. In this series, 28 patients complained of joint pains. There was no abnormality in the 14 patients whose chests were examined by x-ray.

Ulcerative colitis. Six patients with acute or chronic ulcerative colitis developed lesions of erythema nodosum. The chest was examined roentgenologically in only 1 case, in which no abnormality was shown. Another case of ulcerative co-

received 60 gr. of sulfanilamide before the appearance of the erythema nodosum.

In this group of 8 cases, only one roentgenogram of the chest was available, in which no abnormality was noted.

Syphilis. Four patients presented past histories of syphilis, but in none of these was the blood Wassermann or Kahn test positive. Roentgenographically, 1 case (Case 4, Table 2) showed a resolving left-lower-lobe pneumonia, with moderate enlargement of the bronchial nodes bilaterally. Chest roentgenograms of 2 other patients in this group showed no abnormality.

Gonorrhea. None of the 4 patients with past histories of gonorrhea showed evidence of active

FIGURE 1.

The x-ray film on the left shows enlargement of the mediastinum and hilar lymph nodes in a case of erythema nodosum in which there was no demonstrable associated pulmonary disease; the film on the right was taken four weeks later, when there was essentially no adenopathy.

litis, which was not included in this survey, developed lesions that resembled erythema nodosum, but the diagnosis of acute perivascularitis was not excluded.

Drug ingestion. In only 2 patients of a group of 8 with a history of drug ingestion was there strong evidence that the eruption was due to drug intoxication. In both cases, bromides were found in the urine, and in 1 there was a past history of veronal poisoning. The drugs that were found to be related to or ingested prior to the appearance of erythema nodosum were bromides, coal-tar derivatives, potassium iodide, sulfanilamide, Neoprontosil and sulfathiazole. One patient received therapeutic doses of sulfanilamide for three days before the onset of the eruption. This patient was being treated for a prostatic abscess. Another had

infection except, perhaps, for the patient with a prostatic abscess, alluded to previously, who received sulfanilamide prior to the occurrence of erythema nodosum.

Herpes zoster. One patient developed herpes zoster on the dorsum of a hand in the same region as the lesions of erythema nodosum twenty-six days after the onset of the erythema. The roentgenogram of the chest was normal.

Measles and otitis media. One patient stated that the onset of erythema nodosum was preceded by measles and bilateral otitis media three weeks and two weeks, respectively, before hospitalization. The chest roentgenogram was normal.

Eye diseases. Conjunctivitis was present in 4 cases. One of these patients had ulcerative colitis a year previously. Another developed an epi-

scleritis during the course of the eruption, and also developed iridocyclitis two months following discharge from the hospital. Of this group of 5 patients, chest films were available in 4 cases, none of which showed any abnormality.

Prostatic abscess. This patient, previously referred to in the section dealing with drug ingestion, stated that he had had gonorrhea thirty years before entering the hospital in 1940 with a prostatic abscess. Roentgenologic examination of the chest was not performed on this patient.

Postoperative infection. Erythema nodosum lesions were described in a patient who had developed a wound infection following a surgical procedure for repair of an incisional hernia.

Axillary abscess. One patient, a nurse, developed erythema nodosum during the course of an axillary abscess. An axillary lymph node was removed histologically, and the findings are described below. The chest of this patient was not examined roentgenologically.

Peritonsillar abscess. While being treated for a peritonsillar abscess, one patient developed the lesions of erythema nodosum. Roentgenologic examination of the chest showed no abnormality.

Tuberculin Tests

Of the forty-four tuberculin tests* that were performed on half the patients, thirty-three were positive. No tests were performed subsequent to discharge from the hospital.

Previous Attacks

Five patients entered the hospital with histories of previous episodes of erythema nodosum. Three patients stated that they had had two, four and five previous attacks respectively, whereas 2 claimed that they had had one previous attack each. Another case had a questionable previous attack.

Subsequent Attacks

Two patients of the group returned with attacks of erythema nodosum. The patient with evidence of bilateral fibrocalcific tuberculosis developed three subsequent crops of erythematous lesions within a period of about five months following the initial episode of erythema nodosum.

History of Exposure to Tuberculosis

Three patients presented evidence of contact with tuberculous patients; only 1 of these showed slight enlargement and calcification of the hilar lymph nodes. Five patients entered the hospital with histories suggestive of possible contact with tuberculosis, 3 of whom roentgenologically showed intrathoracic abnormalities.

*O.T. (old tuberculin) is used for these tests; in children and in adults in whom tuberculosis is suspected, the initial dilution is 1:100,000, and in other adults, 1:10,000, a test is not reported "negative" until a 1:1000 dilution has been employed.

Communicability

Two employees of the Mount Sinai Hospital who were roommates developed erythema nodosum lesions five days apart. In both, there was a history of an upper respiratory infection preceding the eruption.

Biopsy

Biopsies were performed in 10 of the 88 cases of erythema nodosum. Specimens were taken from the skin in 8 cases and from lymph nodes in the axilla in 2. The microscopic findings in the skin sections in all cases were those of erythema nodosum. In 1 case with concomitant lymphadenopathy, an axillary lymph node that was removed showed nonspecific hyperplasia. The lymph node removed from a patient with an axillary abscess of a few months' duration showed nodular areas with small central abscesses. Epithelioid cells were seen, but no tubercle bacilli were present.

Subsequent Case Records

Thirty-four patients returned for follow-up examinations. One patient subsequently showed questionable evidence of rheumatic heart disease, and another returned seven years later with an episode of acute rheumatic fever with joint symptoms. Hypertension was noted in 2 patients who reported for examinations following discharge from the hospital. Two others returned with recurrent episodes of eruptions diagnosed as erythema nodosum.

Roentgenologic Features

Chest roentgenograms were available in 56 of the 88 cases. Fourteen of these were associated with pulmonary changes or enlargement of the intrathoracic lymph nodes, or both.

There was roentgenologic evidence of enlargement of mediastinal or lymph nodes, or both, in 12 patients, 3 of whom showed calcification in the nodes.

The hilar shadows were accentuated in 2 cases, and in another there was unusual exaggeration of the pulmonary markings in both upper lobes.

A resolving pneumonic process was noted in 1 case.

In the presence of a clinical diagnosis of childhood tuberculosis, the roentgenogram showed a pneumonic infiltration of the left upper lobe.

A young patient who later died of hematogenous miliary tuberculosis showed nodular infiltrations throughout both lungs.

A thirty-four-year-old woman whose chest roentgenogram revealed fibrocalcific tuberculosis of both upper lobes on several occasions developed episodes of erythema nodosum. The chest findings remained unchanged.

TABLE 2 Data on Patients with Associated Intrathoracic Changes

CASE No.	HOSPITAL No.	DATE OF ADMISSION	SEX	AGE	CHEST ROENTGENOGRAM	TUBERCULIN TEST	COMMENT	SUBSEQUENT COURSE
1	320104	2/20/30	F	40	2/21/30 moderate enlargement of left hilar lymph nodes	Not done	Four previous attacks of erythema nodosum during previous 30 years tonsillitis preceded these attacks	March 1931 no recurrence after removal of tonsillar rings
2	35070	4/8/33	F	9	4/10/33 slight enlargement of hilar lymph nodes with calcification calcified primary infection left base slight elevation of pericardium on anterior aspect of right tibia beneath soft tissue swelling of erythema nodosum lesion	Positive	Mother of patient receiving pneumothorax therapy for pulmonary tuberculosis	1934 another attack of erythema nodosum chest roentgenogram showed no change
3	359578	11/23/33	F	5	11/23/33 slightly enlarged hilar nodes particularly on left side	Strongly positive	Generalized lymphadenopathy	1938 chest roentgenogram revealed no change systolic murmur persists rheumatic heart disease (?)
4	361770	1/20/34	F	30	1/22/34 moderate enlargement of bronchial lymph nodes bilaterally with slight calcification resolving left lower lobe pneumonia	Positive	Systolic murmur at apex biopsy of skin on two occasions showed changes consistent with diagnosis of erythema nodosum intravenous and intramuscular therapy given 10 years previously following two miscarriages blood Wassermann reaction negative	4/2/34 no complaints
5	364252	3/30/34	F	29	4/4/34 right bronchial and para tracheal lymph nodes enlarged	Not done	Cervical lymph nodes palpable sister died of tuberculosis 25 years previously	Patient failed to report for follow up
6	366529	5/23/34	F	13	5/25/34 calcified lymph nodes at both lung roots prominence of pulmonary conus	Positive	Bilateral submandibular and axillary adenopathy systolic murmur at base (rheumatic heart disease?) electrocardiogram normal	Patient failed to report for follow up
7	375748	1/17/35	M	9	1/19/35 pneumonic infiltration extending from left hilum to periphery of lung in midportion of left upper lobe, enlarged left hilar nodes	Strongly positive	Bilateral cervical and epitrochlear lymphadenopathy clinical diagnosis childhood pulmonary tuberculosis	1/31/35 chest roentgenogram showed moderate decrease of pneumonic infiltration in left upper lobe no subsequent record
8	378461	4/5/35	M	13	4/6/35 unusual exaggeration of pulmonary markings of both upper lobes	Positive	Systolic and presystolic murmur (rheumatic heart disease)	1941 no cardiac murmurs
9	412329	8/3/37	F	25	8/4/37 left hilar lymph nodes enlarged	Positive	Chest roentgenogram of patient's father showed evidence of old and questionable recent tuberculosis	November, 1937 pain in region of left upper lobe with slight fever four weeks previously
10	421390	3/14/38	F	16	3/17/38 lateral roentgenogram showed enlarged tracheobronchial lymph nodes prominent pulmonary conus	Positive	Cervical adenitis systolic murmur at apex, 1933 attack of erythema nodosum	June 1939 occasional at thalragias heart normal
11	433021	12/3/38	M	6	12/6/38 widening superior mediastinum bilaterally due to enlarged nodes exaggerated pulmonary markings somewhat nodular in character, particularly on right side 12/24/38 widespread nodular infiltrations bilaterally nodes enlarged, 1/11/39 no essential change	Strongly positive	Rachitic chest deformity spleen palpable, clinical diagnosis miliary tuberculosis	Death at Seaview Hospital on August 3, 1939 post mortem findings diffuse hematogenous miliary tuberculosis, lungs showed miliary tuberculosis and the enlarged hilar and mediastinal lymph nodes revealed caseous tuberculosis
12	453063	2/28/40	F	25	3/7/40 hilar shadows accentuated on both sides moderate enlargement of mediastinal and hilar lymph nodes	Negative	Residual strabismus from attack of meningitis at age of 2	2/3/41 almost complete regression of previous chest findings
13	476893	7/28/41	F	32	8/1/41 distinct exaggeration of right hilar shadows and slight widening of superior mediastinum to the right appearance most likely due to enlarged hilar and para tracheal lymph nodes	Strongly positive	Skin biopsy not reported, past history "water on kidney" 10 years previously	November, 1941 patient recently admitted to another hospital with hydropneumothorax and hypertension
14	374634	5/7/41	F	34	5/21/41 fibro-sclerotic foci in both upper lobes no definite recent infiltration	Strongly positive	Skin biopsy showed changes due to erythema nodosum	November 1941 patient subsequently developed new crops of erythema nodosum on three occasions in previous 5 months

Table 2 presents a more detailed analysis of the 14 patients with intrathoracic changes.

In view of these findings, it is obvious that roentgenologic examination of the chest should be performed in all cases of erythema nodosum, even in the absence of chest complaints. Examination of the chest in the lateral position should be included. In our experience, in the 1 case in which a roentgenogram in this position was available, an enlarged lymph node was demonstrated, although the routine posteroanterior film failed to reveal it. It is probable that had the chests been examined in both positions routinely, more cases with enlarged intrathoracic nodes might have been discovered. In questionable cases of enlargement of the intrathoracic lymph nodes, more information may be secured by fluoroscopy and sectional radiography, and perhaps also by kymography.

SUMMARY AND CONCLUSIONS

A survey of 88 cases of erythema nodosum indicates that the condition may be found during the course of various diseases, both infectious and noninfectious, virus, bacterial, chemical and toxic. It is evident that no common agent causes these diseases that might be expected to be the cause of erythema nodosum. In a small group of patients (approximately 15 per cent), no evident associated disease was present.

The following conditions were associated with the erythema nodosum in these 88 cases: tuberculosis (4 cases); rheumatic heart disease (7 definite and 10 questionable cases); ulcerative colitis (6 cases); upper respiratory infections (49 cases); arthralgias (28 cases); drug ingestion (8 cases); inactive syphilis (4 cases); gonorrhea (4 cases); herpes zoster (1 case); measles and otitis media

(1 case); eye disease (1 case); prostatic abscess (1 case); postoperative infection of abdominal wall (1 case); axillary abscess (1 case); and peritonsillar abscess (1 case).

Fourteen of fifty-five available chest roentgenograms revealed positive intrathoracic findings. Twelve showed slight to moderate enlargement of the nodes, three with calcification. Pulmonary abnormalities were noted in 5 cases—resolving pneumonic process, pneumonic infiltration, exaggerated pulmonic markings, miliary tuberculosis and fibrocalcific tuberculosis. Tuberculin tests, which were performed in 12 of the 14 patients, were positive in 11.

The patients whose roentgenograms showed intrathoracic adenopathy or pulmonary infiltration, or both, had associated disease of the respiratory tract that could account for the abnormalities and often obviously did. In the cases in which the development of erythema nodosum was associated with ulcerative colitis, prostatic abscess, peritonsillar abscess, rheumatic heart disease, gonorrhea, conjunctivitis, postoperative infection, axillary abscess, measles and otitis media, and ingestion of drugs, the chest roentgenograms failed to demonstrate any pulmonary changes or intrathoracic lymphadenopathy.

A PRACTICAL OUTLINE FOR THE TREATMENT OF BURNS*

DONALD W. MACCOLLUM, M.D.†

BOSTON

FOR several years before the present war, the number of people in this country who died each year from burns ranged in the vicinity of 6000. In addition, 1500 died each year as a result of conflagration, and untold thousands lived but were permanently disfigured or deformed. Since burns are not acquired or inherited like disease, but are almost always purely accidental, more and more rigid safety measures have been instituted both in the home and in industry in an attempt to reduce these figures. Obviously, if fewer people were burned, there would be fewer deaths, but prevention is only one of the two significant factors concerned in this high death rate. The other, equally important, factor is a proper appreciation of how to handle the burned patient from a medical standpoint. To lessen the incidence of confused, unintelligent and inadequate care by the layman, nurse and physician alike would effect an appreciable reduction in the number of fatalities and deformities caused by burns.

During peacetime, 83 per cent of all burns occur in the home, 10 per cent in industry, and 7 per cent in public accidents. It is obvious from these figures that there is a great need for both an educational program and the elimination of physical hazards in every home. This is to be kept in mind now and after the war is over. However, in wartime, with the possibility that explosive and incendiary bombs will drop on civilian rather than on military lines of defense, the number of burn casualties is in danger of being greatly increased. This has been true in every country that has experienced any number of air raids. For this reason, every person should have some knowledge of what to do and, perhaps more vital, what *not* to do for a person who has been burned.

The Red Cross and the Office of Civilian Defense have accepted and are discharging a tremendous responsibility in training a large number of laymen in the rudiments of first aid. Every physician in the country has also been preparing and refreshing his mind, so that he will be equipped to take care of war casualties.

In line with this general preparation, the follow-

ing condensed outline for the treatment of burns has been drawn up, based on experience both personal and collective, to aid in the rapid assimilation of the present knowledge on this subject.

I. THERMAL BURNS (HOT LIQUIDS, STEAM, FLAME, AND HOT METALS)

1. First-Aid Instructions for Laymen.

- a. Treat all burned patients for shock.
- b. If a physician is not present but is available:
 - (1) Cover small burns with a clean cloth or sterile bandage, and take the patient to the first-aid post.
 - (2) For extensive burns, cover the patient with a clean sheet and blankets; bring the doctor to the patient, if possible—otherwise send the victim to a hospital immediately.
 - (3) Do *not* put tannic acid ointment on any burn.
- c. If a physician is neither present nor available and it seems likely that one or two hours may elapse before the patient can be seen by a physician:

(1) For small burns, clean the area by gently washing with a mild soap under running water—if running water is not available, do not clean, but cover the burn with a paste of sodium bicarbonate and water; wrap the burned area securely in clean or sterile cloths, and send the patient to a physician.

(2) For extensive burns, remove the clothing but do not try to clean the area; cover the burned parts with clean cloths (napkins, pillow cases or sheets) soaked in a warm solution of sodium bicarbonate—cover with dry cloths; keep the patient warm and get him to a hospital as soon as possible; give strong coffee or tea by mouth.

d. Important points to be remembered:

- (1) Do *not* apply tannic acid jelly or strong tea to a burn until after the burn has been properly cleaned by a doctor.
- (2) Do *not* apply grease in any form.
- (3) Do *not* move the patient about in an attempt to put on a neat bandage; disturb him as little as possible.

*Presented in part at the annual meeting of the Massachusetts Medical Society, Boston, May 27, 1942.

†From the Department of Surgery, Harvard Medical School, and the Surgical Service of the Children's Hospital and of the Peter Bent Brigham Hospital.

‡Associate in surgery, Harvard Medical School; associate visiting surgeon, Children's Hospital; associate in plastic surgery, Peter Bent Brigham Hospital.

2. First-Aid Instruction for Physicians.

a. Check all patients with minor or major burns for shock; treat this even before the burned area is examined.

b. Give morphine liberally: administer a dose double that which would normally be used for the patient if he were to have a preoperative dose for an elective operation.

c. If shock is severe, administer oxygen by mask or tube and give caffeine intramuscularly; if plasma is available, give 5 cc. per pound of estimated body weight intravenously; if plasma is not available, give physiologic saline solution—10 cc. per pound of body weight—while plasma is being obtained.

d. When shock has been effectively combated, carefully remove the bandages and clothes; examine the burn and try to estimate extent and depth of the burn.

e. If the burn is minor:

(1) Cleanse thoroughly by washing gently for about seven minutes with sponges soaked in 50 per cent green soap (solution, not tincture) and 50 per cent hydrogen peroxide.

(2) Break all blisters, and remove all dead skin and debris (use sterile instruments).

(3) Flush with copious amounts of physiologic saline solution, or distilled water, and dab dry.

(4) Dust the area with sulfathiazole, sulfadiazine or sulfanilamide powder.

(5) For burns of the hands, feet, face and genitalia, apply a sterile ointment and cover as well as possible with sterile gauze and bandage.

(6) For burns elsewhere on the body tannic acid jelly or triple-dye jelly may be used; cover with sterile gauze, apply an Ace bandage, and splint the part involved.

f. If the burn is major:

(1) Remove the clothes sticking to the burn and gross dirt or contamination, but do *not* clean *extensively*.

(2) Dust the area liberally with sulfathiazole, sulfadiazine or sulfanilamide powder (if a 5 per cent sulfadiazine, water-soluble jelly or emulsion is available, this may be used instead of the powder).

(3) If the powders are used, cover the area with a liberal amount of water-soluble glycerin-tragacanth jelly (if this jelly is not available, any sterile ointment or triple-dye

jelly can be used; however, the latter are harder to remove when the burn receives its final débridement).

(4) Apply heavy (5 to 7 cm. thick) sterile gauze pads and hold them securely in place under mild pressure with an elastic bandage.

(5) Evacuate the patient to a hospital as quickly as possible.

g. Important points to be emphasized:

(1) Do *not* fail to appreciate the fact that shock must be treated *first* and that examination of the burn should wait until the patient is fairly well recovered from the shock.

(2) Do *not* apply tannic acid in any form until *after* the burn has been *thoroughly* cleansed; never apply it to the hands, face, feet or genitalia.

(3) Do *not* temporize with morphine—give it either in a large enough dose to do some good or not at all.

(4) Do *not* allow the sulfonamide powders to get into the eyes or up the nose (they irritate as foreign bodies).

(5) Do *not* fail to apply a *thick* dressing under mild pressure.

3. Hospital treatment of fresh burns.

a. For minor burns treat the patient as outlined above (Section I, 2e, 1-6).

b. For major burns:

(1) Check on the degree of shock still present; administer more morphine, heat and so forth, as required.

(2) If time permits and facilities are available, obtain a red-cell count, hemoglobin determination, hematocrit reading and a serum protein (one or more of these are helpful in determining the degree of hemoconcentration).

(3) Give an initial intravenous infusion of plasma of 3 to 5 cc. per pound of estimated body weight; have more plasma available if it is needed; whole-blood transfusion is not indicated unless there has been appreciable blood loss from some other source; if whole blood is available but no plasma, make an effort to separate the plasma from the red cells by centrifugalization or otherwise.

(4) After shock is well controlled, the patient may need to be anesthetized for proper cleaning; use rectal or intravenous anesthetics for those who may have inhaled hot air or gases.

(5) Wash burned area thoroughly for seven minutes with a mixture of solution of green soap and hydrogen peroxide (equal parts)

(6) Remove all dead skin and debris, use sterile precautions throughout debridement

(7) Flush thoroughly with physiologic saline solution and, if desired, some mild antiseptic, such as a 1:1000 solution of Zephiran or Merthiolate, or ST 37

(8) For burns of the hands, feet, face and genitalia, dust the area with one of the sulfonamide powders and cover with a sterile ointment (*tulle gras*) and a heavy layer of gauze sponges held in place by an elastic bandage, splint the hands and feet

(9) For burns elsewhere on the body, the treatment outlined in Section I, 3b, 8, may be used, provided adequate facilities are at hand to combat fluid loss by repeated plasma transfusions

(10) For burns elsewhere on the body, the escharotics are usually employed, principally 5 per cent tannic acid followed by 10 per cent silver nitrate, the triple dyes or a sulfadiazine spray, whichever method is used, specialized aftercare is required, a clean or sterile electrically heated bed, frequent evaluation of the blood chemical findings, adequate fluid intake enterally and parenterally, and constant nursing and medical appreciation of the problems for each case

4 Hospital Treatment of Old Burns

a If a sulfonamide powder has been used in the first aid treatment, a débridement as outlined in Section I, 3b, 4-7, may be carried out as late as thirty hours after the burn was received

b If a sulfonamide has not been used, a complete operative débridement is contraindicated if the burn is eight or more hours old. In this event, the following procedure is advised

(1) Give shock treatment as outlined in Section I, 3b, 1-3

(2) Immerse the patient in a tub of warm tap water for one or two hours, with constant inflow and outflow of water

(3) Remove the patient from tub, dab dry and spray with one of the sulfonamide powders

(4) Either cover the burns with an ointment (preferably *tulle gras*) or use the triple

dye jelly or sulfadiazine spray, do *not* use tannic acid in any form

(5) As an alternative to the procedure outlined immediately above, one may use dressings wet with physiologic saline solution, a Bunyan envelope or *tulle gras* with Eusol (125 gm chlorinated lime, 125 gm boric acid and 1000 cc distilled water—let the mixture stand twenty four hours, then filter and keep in a tightly corked bottle), if the burn is coated heavily with fibrin and pus, one of the latter is preferable *first*, to be followed later by a sulfonamide powder

c In second degree burns, healing takes place without grafting over a period of ten days to two weeks

d In either superficial or deep third degree burns (so called "third degree," "fourth degree" and "fifth degree," according to one system of classification), grafting may be necessary, depending on the extent and site involved

e If grafting is necessary, certain precautions must be observed before proceeding

(1) The patient must be free from infection, in good health and with a normal red cell count

(2) An estimate of the amount of tissue to be replaced must be made, and a program outlined for its transfer

(3) The granulations must be flat, firm and cherry pink

(4) The granulations should be removed down to the fibrous tissue base from which they spring, and depending on the site involved, this fibrous base may also be removed

(5) For defects involving the loss of skin only, a thin or thick razor graft (Thiersch or split Thiersch) is preferable

(6) For small areas involving the skin of the face or hands, a full thickness graft (Wolfe or Wolfe-Krause) may be used interchangeably with the thick razor graft

(7) For areas involving the loss of both the skin and subcutaneous tissue, a single hinged or double hinged pedicle flap (pedicle, gruntlet, tube or rope) must be used

(8) Bone, cartilage and fascia may also be replaced, but this is usually done six to eight months after the skin defects have healed

(9) Do *not* use island grafts (pinch, Reverdin, small deep and Davis grafts) unless

nothing else is possible; there is seldom occasion for their use.

II. CHEMICAL BURNS

(Whoever treats chemical burns should take adequate precautions to protect himself.)

1. Mustard Gas.

a. First aid for exposure to mustard-gas vapor (one to eight hours).

(1) Remove and place all clothes in decontamination bucket.

(2) Give a thorough soap-and-water bath, including shaving or clipping short of all hair and rewashing these areas.

(3) Apply a bleaching-powder wash, followed by a second soap-and-water cleansing.

(4) Keep the patient under observation for twelve hours; if there is no rash or blisters at the end of that time, the patient may be discharged.

b. Late treatment for exposure to mustard-gas vapor (eight hours and over):

(1) Treat the patient for shock; rash and blisters have appeared over warmed areas of the body (axilla, groin and so forth), with severe itching and beginning shock.

(2) Do *not* sedate heavily with morphine (pulmonary complications due to inhalation of the gas may be increased by a lowered respiratory rate).

(3) Anesthetize by the rectal or intravenous route, if necessary.

(4) Clean the burn thoroughly, as outlined in Section I, 3b, 5-7.

(5) Apply *tulle gras* over all raw surfaces and follow with a heavy dressing wet with equal parts of Eusol and mineral oil.

(6) Apply a heavy dressing, held in place with gauze and an Ace bandage under mild pressure.

(7) Follow the routine outlined for the aftercare of second-degree or third-degree thermal burns (Section I, 4e, 1-9).

(8) For very late infected cases seen two or three days after exposure, follow the routine outlined in Section I, 4b, 1-3, 5.

c. First aid for contact with mustard-gas liquid.

(1) Within five minutes, *blot* off excess mustard gas by dabbing with dry pads.

(2) Dab the area gently and repeatedly with pads moistened in kerosene, gasoline or alcohol; wring the pads out so that excess liquid will not drip on the patient and spread the burn.

(3) Thoroughly wash the entire area with a mixture containing equal parts of green soap and peroxide.

(4) Wash the area again with alcohol.

(5) Dry by blotting, and apply a dry dressing that is to be removed and the area examined every two hours for the next twelve hours; if the area looks normal at the end of twelve hours, the patient may be discharged.

d. Late treatment for contact with mustard-gas liquid.

(1) If blisters have formed, dab with pads of kerosene gently to get rid of excess liquid; do *not* use a bleaching agent.

(2) There is no need to sedate heavily or anesthetize (the area is usually painless after liquid has penetrated through the skin).

(3) Carry out full *débridement* as outlined in Section I, 3b, 5-7, and follow with a *tulle gras* and Eusol dressing.

(4) In very late cases when the blisters have broken and have become infected, carry out the routine outlined in Section I, 4b, 2, 3, 5.

(5) In the late cases, as soon as the fibrinous infected coat has been removed from the raw surfaces by the Eusol, the sulfonamides may be used.

(6) Late care, including grafting, is the same as that for thermal burns.

2. Lewisite.

a. First aid for exposure to lewisite vapor.

(1) Remove clothing at once.

(2) Wash entire body with hydrogen peroxide; follow this with a complete and thorough bath with soap and water and an alcohol sponging.

(3) Keep the patient under observation for 12 hours; if no blisters appear, he may be discharged.

b. Late treatment for exposure to lewisite vapor.

(1) Sedate and give a rectal or intravenous anesthetic if burns are extensive.

(2) Wash around and over each blister with soap and hydrogen peroxide; be very gentle.

(3) Break the blister, being very careful to catch all the blister fluid on a sponge (throw sponge in decontamination bucket); immediately apply a pad wet with hydrogen peroxide to the raw area; renew this pad frequently.

(4) After all blisters have been broken and covered with a pad of hydrogen peroxide, carry out full operative débridement as outlined in Section I, 3b, 5-7.

(5) Cover the burn with a *tulle gras* and Eusol dressing, thick gauze and an Ace bandage.

(6) If the burn remains clean, reapply the dressing described in Section II, 2b, 5, each day.

(7) If the burn becomes infected, the treatment is the same as that outlined in Section I, 4b, 2, 3, 5.

c. First aid for exposure to lewisite liquid

(1) Within one minute after exposure remove the clothes and start treatment.

(2) Swab area with hydrogen peroxide repeatedly for thirty minutes.

(3) Wash with soap and water for seven minutes, and follow with an alcohol pad, which is left in place for five minutes.

(4) Pat dry, and apply a dry dressing, if no blisters have formed at the end of twelve hours, the patient may be discharged, if blisters have formed, carry out the routine outlined in Section II, 2b, 2-4, except that anesthesia is usually not necessary.

d. Late treatment for exposure to lewisite liquid

(1) If an unbroken blister is found, carry out the routine outlined in Section II, 2b, 1-7.

(2) If the blister has broken and the patient shows signs of arsenical poisoning, excise entire area under anesthesia at once, and follow by grafting as outlined in Section I, 4e, 5-8.

(3) If the area is too extensive for excision and is grossly infected, the prognosis is poor, however, treat the patient as outlined in Section I, 4b, 2, 3, 5 and attempt to control the arsenical poisoning by intravenous sodium thiosulfate.

3 Phosphorus

a. If there is no phosphorus that is still burning in or on the skin, treat the burn as a thermal one (Section I).

b. If bits of phosphorus that are still smouldering lie on or in the skin:

(1) Wet the area and keep it wet with anything, but preferably warm water (this melts and stops further burning of the

particles; if the area becomes dry, the particles will begin to burn again).

(2) If a 5 to 15 per cent solution of copper sulfate is available, apply this at once (burning is stopped temporarily).

(3) No matter which of the above methods is used, squeeze or pick out the phosphorus particles with forceps and then treat as any thermal burn.

4 Acids and Alkalies

a. Remove the patient's clothing at once, taking care that the chemical agent does not burn others.

b. Flush area under cold running water (the heat of dilution of strong chemicals is carried away by the continuous washing); if running water is not available, douse the patient in a tank, tub, or lake, if the burn is due to lime, brush off the excess before wetting.

c. Do not attempt to neutralize the burning agent (the heat of reaction may cause a deeper burn, or the neutralizing agent itself may burn).

d. After removal of the burning agent, treat as a thermal burn (Section I).

III ELECTRICAL BURNS

1 General Effects.

a. Do *not* touch a patient who is still in contact with the electric current, unless proper insulation is possible.

b. Never regard a recently shocked person as dead, even if the heart beat cannot be heard.

c. Continue artificial respiration, oxygen and cardiac stimulants until rigor mortis sets in (several patients have recovered after having been apparently dead for hours).

2 Local Effects.

a. Except for a very few cases almost all electrical burns are of third degree, owing to the intense heat and the coagulation of blood in the vessels supplying the area involved.

b. Do *not* be misled by the apparently innocuous appearance of the fresh electrical burn, institute treatment at once:

(1) Sedation or anesthesia is rarely necessary.

(2) Clean the area thoroughly with a mixture of green soap and hydrogen peroxide and flush with saline.

(3) Apply a sterile ointment, gauze and an elastic bandage; splint the part involved.

(4) Do *not* apply any substance that will form an eschar.

(5) Apply daily dressings under strict aseptic precautions so that the amount of late necrosis and slough may be observed.

(6) Do *not* cut away sloughing tissue; allow the demarcation and detachment of dead tissue to take place without surgical aid (hasty operative removal may result in excision of tissue that will be viable and necessary for repair).

(7) Vessel walls are damaged, so that secondary hemorrhage is frequent; have a

sterile tray with hemostats and a tourniquet always at the bedside.

(8) After the slough has disappeared, treat as in Section I, 4e, 5-8.

A general survey of the treatment of burns has been outlined, with particular emphasis on the treatment of shock, the need for gentleness in the handling of tissues and the necessity for a complete cleansing of the burned area before medicaments are applied. Each burn presents an individual problem; consequently, it is impossible to outline specific details for every possible type of burn. The broad general principles have been stressed, in addition to specific instructions that, if followed within reason, will cause an appreciable reduction in the number of fatalities.

MEBARAL IN THE TREATMENT OF EPILEPSY*

BENJAMIN COHEN, M.D.,† AND ABRAHAM MYERSON, M.D.‡

BOSTON AND NORTH GRAFTON, MASSACHUSETTS

IN 1929, the drug known in this country as Mebaral was introduced in Europe under the name of Prominal, the chemical formula being *n*-methylethyl-phenyl barbituric acid. It has been utilized in Europe quite extensively, but its introduction in the United States is recent, so that it is not sufficiently known to the medical profession in this country. Mebaral is supplied in tablets of 0.03 gm. ($\frac{1}{2}$ gr.) and 0.2 gm. (3 gr.) on the erroneous supposition that it is half as potent in sedative qualities as phenobarbital, to which it is closely related chemically. In general, it may be stated that its sedative effect is about one third that of phenobarbital.

In 1932, Weese¹ pointed out that the spans between the hypnotic, narcotic and lethal doses of Mebaral are greater than those of phenobarbital, that is, the margin of safety is greater. In the same year, Blum² reported that he had tried Mebaral for three years on several hundred epileptic patients in his hospital and private practice. He found that 0.2 gm. (3 gr.) two or three times a day decreased the epileptic seizures about 50 per cent. He found it valuable in petit mal as well, and observed no hypnotic effects. Heyde³ considered Mebaral slightly superior to phenobarbital as an anticonvulsant, but greatly superior in the treatment of psychic symptoms in epilepsy.

He favored it for the treatment of ambulatory and noninstitutional patients.

Plaut,⁴ in 1935, stated that the drug was very useful as a sedative, his material being 60 patients suffering from insomnia, nocturnal enuresis, hyperthyroidism and various psychoses. Using it in dosages of 0.1 to 0.2 gm. ($\frac{1}{2}$ to 3 gr.) a day, he found no serious by-effects and noted that employed patients were not incapacitated by drowsiness.

Page,⁵ in 1936, compared his findings with Mebaral and phenobarbital during equal five-month periods. In the period under phenobarbital administration, the patients had a total of four hundred and seventy-six grand-mal seizures. In the second period, under the influence of Mebaral, the same patients had two hundred and forty-four grand-mal attacks. Page also noted that under Mebaral the patients were bright and cheerful, and could care for themselves.

Henderson,⁶ in 1937, selected 13 patients with grand-mal epilepsy who had not shown sufficient improvement on clinical trial with other drugs, and, during a period of twelve months' administration with Mebaral, noted a two-thirds reduction in the number of attacks as compared with those in the previous period. He found that 0.6 gm. (9 gr.) a day was apt to cause drowsiness, and believed that the optimum clinical effects were obtained with 0.4 gm. (6 gr.) a day. His patients did not suffer from gastrointestinal disturbances, urinary changes, or significant fluctuations in blood pressure, and they did not develop a tolerance that required increased dosage. In a few

This study was aided by grants from the Commonwealth of Massachusetts and the Rockefeller Foundation.

†Formerly, senior physician, Grafton State Hospital.

‡Professor emeritus of neurology, Tufts College Medical School; clinical professor of psychiatry, Harvard Medical School; director of research, Boston State Hospital.

cases of petit-mal epilepsy, he was not able to produce favorable changes.

Millman⁷, in the same year, reviewed the comparative findings in 39 patients previously on phenobarbital whose medication had been changed to Mebaral with a gradual increase in dosage 50 per cent greater than that of phenobarbital. There was a great reduction in both grand-mal and petit-mal attacks, the average reduction being slightly less than two thirds. Of 27 patients who showed abnormal behavior and were considered to be epileptic equivalents, or psychic manifestations, there was improvement in 19. Many of the adults were given 0.6 gm. (9 gr.) a day for two years, without ill effects. In children, he employed the formula, age—age + 12, to determine the fraction of the adult dose that they should receive. In a few adults receiving maximum dosage, he noted drowsiness, which disappeared when the drug was withheld for a few days.

Our own experience with this drug is threefold. Concerning its value in agitated, depressed and anxiety states, about which we shall report at a later date, it suffices to say that this drug seems to us to be by far the best sedative in the treatment of these conditions, since it produces more tranquility and less narcosis than any other drug, and without untoward symptoms unless given in doses above 0.4 to 0.6 gm. (6 to 9 gr.) a day. Secondly, since the treatment of epileptics in private and outpatient practice is not methodically controlled, it cannot be analyzed well. The impression of both of us is that this drug is efficacious in the treatment of epilepsy, of both the grand mal and the petit-mal types, and that it has fewer undesired effects than either phenobarbital or Dilantin, its chief rivals in the treatment of epilepsy. The third group consists of controlled epileptic patients at the Grafton State Hospital, with which this paper is mainly concerned.

The last group has been known to us for years and represents a group relatively refractory to other drugs. The rate of convulsive expectation had been established over periods of six months to three years of observation. These patients had had previous treatment in this hospital with phenobarbital alone, and with phenobarbital and Dilantin; we here record the experimental treatment with Dilantin and Mebaral, and with Mebaral alone. The comparison is made between the effects of the former two drugs and those of Mebaral on the incidence of epileptic attacks in these patients as compared with the effects of previous drugs used. We are thus not comparing the effects of Mebaral on cases easily controlled by phenobarbital or Dilantin, or by phenobarbital

and Dilantin, but on patients who had not done well on these drugs.

The results of our investigations in these relatively refractory patients may be stated as follows. Of 12 patients who had trial treatment separately with phenobarbital and with Mebaral, 2 did better with the former, and 10 with the latter. On Mebaral alone, there were 42 per cent fewer seizures than with phenobarbital. Nine patients had separate trials of phenobarbital and Dilantin and of Mebaral alone. Two did better with the former, and 7 with the latter. On Mebaral alone, there were 48 per cent fewer seizures than with phenobarbital and Dilantin. Eleven patients had separate trials with a combination of Dilantin and Mebaral and with Mebaral alone. Four did better on the latter, and 7 on the former. There were 38 per cent fewer seizures on Mebaral alone.

The average period for any treatment ranged from twenty seven weeks to one year. We con-

TABLE 1 Comparative Effects of Desultory Preliminary Medication and Concentrated Individualized Therapy with Phenobarbital, Phenobarbital and Dilantin, Dilantin and Mebaral, and Mebaral

PATIENT	AVERAGE NUMBER OF SEIZURES PER TEN WEEKS

sidered these periods sufficient for determining the value of any drug or set of drugs in patients having frequent attacks.

The dosage of phenobarbital given alone was from 0.13 to 0.45 gm. (2 to 7 gr.) per day, the average being 0.27 gm. (4 gr.). When phenobarbital was combined with Dilantin Sodium, the dosage of the former remained unchanged, and 0.2 to 0.4 gm. (3 to 6 gr.) of the latter was added, the average dose of this drug being 0.3 gm. (4½ gr.). When Dilantin and Mebaral* were used, the daily dose of the former ranged from 0.2 to 0.3 gm. (3 to 4½ gr.) a day, the average being 0.25 gm. (3½ gr.) and that of the latter averaged about 0.6 gm. (9 gr.). When Mebaral was used alone, the dose was from 0.4 to 0.8 gm. (6 to 12 gr.) a day, the average being 0.6 gm. (9 gr.).

*Kindly supplied by the Department of Medical Research, Winthrop Chemical Company, New York City.

In Table 1, the column labeled "inadequate phenobarbital therapy" indicates the former incidence of seizures during each ten weeks for periods ranging from six to twenty-four months immediately preceding the institution of the program of intensive individualized therapy, which has been described in a previous paper.⁸ That phenobarbital cannot be discredited is evidenced by the fact that this drug alone in adequate amounts reduced the number of seizures 66 per cent from that obtained by desultory treatment.

In a few patients, Mebaral produced drowsiness and gait disturbance, similar to the effects of phenobarbital, although they were less marked and more easily dissipated. We found that amphetamine (Benzedrine) sulfate, in doses of 10 to 20 mg. by mouth, was equally useful in such cases as a therapeutic agent pending the improvement that invariably attended reduction of dosage of Mebaral and rest in bed. In general, such toxic symptoms attended the use of Mebaral much less frequently than the use of phenobarbital, despite the use of proportionately higher dosage.

SUMMARY AND CONCLUSIONS

Attention is called to the value of Mebaral (n-methylethyl-phenyl barbituric acid) in the treatment of epilepsy.

The drug is particularly useful for epileptic children, who prefer tasteless medication, for psychotic epileptics who must be treated by medication concealed in their food, for patients who

cannot be given adequate phenobarbital because of toxic drowsiness and, finally, for trial in patients who do not show satisfactory response after trials of phenobarbital, Dilantin and bromides, separately or in combination.

In certain cases relatively refractory to other medication, significant improvement was noted when Mebaral was utilized.

Mebaral was found to be less productive of toxic symptoms than phenobarbital or Dilantin, and proportionately higher dosage was continued with safety and as great or greater clinical effectiveness.

In the private practice of one of us (A.M.), Mebaral has become the drug of first choice for the treatment and control of grand mal and petit mal. In cases in which it does not work well by itself, it combines very well with Dilantin. In those cases in which it is not effective, it is discarded, and phenobarbital and Dilantin in combination are used.

HYPOCHROMIC ANEMIA WITH KOILONYCHIA (SPOON NAILS)*

Report of a Case

B. G. CLARKE, M.D.†

BOSTON

KOILONYCHIA (spoon nails), an interesting abnormality, is particularly noted in chronic hypochromic anemia. In the case reported below, koilonychia appeared twice during recurring episodes of hypochromic anemia, disappearing each time after successful treatment of the anemia with iron. Hypochromic anemia is due to iron deficiency, which is essentially dependent on chronic blood loss. Women require about four times as much iron until the menopause as men do, so that hypochromic anemia and, consequently, koilonychia are relatively commoner in women.

This case was presented at a clinic during the annual meeting of the American College of Physicians, Boston, April 25, 1941.

†House officer, Massachusetts General Hospital; formerly, clinical clerk, Second and Fourth (Harvard) Medical Services, Boston City Hospital.

CASE REPORT

First admission. A 46-year-old widowed painter and decorator, who had come to the United States from Glasgow at the age of 22, was admitted to the hospital on January 5, 1934, because of gradually increasing shortness of breath, palpitation and mild ankle edema. Three weeks before admission, he noted substernal tightness on exertion. There was no history of weight loss or melena.

Examination showed a middle-aged man with pallor of the skin, a beefy red tongue, slight pitting edema of the ankles and spooning of the nails. The heart was enlarged, and the blood pressure was 110/60.

Examination of the blood showed a red-cell count of 2,300,000 with a hemoglobin of 20 per cent, and a white-cell count of 6000 with 70 per cent polymorphonuclears, 20 per cent lymphocytes and 10 per cent mononuclears. Red cells in the smear showed marked hypochromia, microcytosis and variation in size and shape. There was only a rare

immature cell, and the platelets appeared normal in number. Gastric analysis showed no free acid, fasting or after histamine. The total acidity was 12 units. Six stools were guaiac negative. The nonprotein nitrogen was 31 mg per 100 cc.

The patient was given iron and ammonium citrates 90 gr a day. The reticulocytes reached 67 per cent on the 7th day, and the red-cell count rose to 4,000,000 and the hemoglobin to 72 per cent 5 weeks later, when he was discharged.

Following discharge, the patient was well and continued to work as a painter for 6 years, without symptoms suggesting either anemia or lead poisoning. He took iron pills intermittently. He continued to be extremely careful about the handling of lead paint and since he is an intelligent man, it is likely that his exposure to this toxic substance was minimal for a painter,

neoplasm or polyp. X-ray examinations of the colon and upper gastrointestinal tract were entirely negative. The reflexes were physiologic, and vibration and position sense normal.

On admission, the red-cell count was 2,860,000 with a hemoglobin of 22 per cent and a hematocrit of 19 per cent, the mean corpuscular volume was 65 cubic microns, the mean cell hemoglobin concentration 24 per cent, and the mean corpuscular hemoglobin 16 micromicrograms, indicating severe hypochromic anemia. The white cell count was 4100, with 72 per cent polymorphonuclears, 19 per cent lymphocytes, 8 per cent monocytes and 1 per cent eosinophils. The red cells showed hypochromia and variation in size and shape. 0.4 per cent reticulocytes were present on admission, and platelets were reduced in the smear. At no time were any stipple cells suggestive of lead poisoning seen. Gastric analysis showed a free acid of 0, a total acid of 4 units and after histamine, a free

FIGURE 1 Nails of the Patient before Treatment

although he had followed this trade since the age of 15. About a year following discharge, the spooning of the nails disappeared.

Second admission (February 20, 1941) The patient had remained essentially well until 6 months before entry, when there was an insidious onset of easy fatigue, weakness, shortness of breath and increasing pallor with development again of spooning of the nails. He had very slight ankle edema, but no tingling or numbness of the extremities, soreness of the tongue, gastrointestinal complaints or weight loss. The diet had apparently been adequate. For the preceding 5 or 6 years however the patient had noticed very occasional streaking of the stools with bright red blood.

Examination showed a well-developed and well-nourished but very pale man in no distress. The skin had a slightly yellow tint, but the scleras were clear. The tongue was pale, with slight atrophy along the margins. The heart was slightly enlarged on x-ray and physical examination with a harsh systolic murmur at the apex and base. The blood pressure was 115/60. The spleen was palpable at the left costal margin, but the liver was not felt. There was no edema of the extremities. Spoon-like concavity of the fingernails was marked (Fig 1), with cracked margins but no longitudinal striations. Rectal examination revealed skin tags at the anus and moderate-sized internal hemorrhoids with several bleeding points. Proctoscopy on three occasions showed no rectal ulcers

acid of 5 units, and a total acid of 10 units. Sixteen stools were guaiac negative, one showed a blood-streaked exterior and was guaiac positive. The icteric index was 4. Liver function studies including hippuric acid excretion and urobilinogen determinations, were normal. The total protein was 6.3 gm and the nonprotein nitrogen 27 mg per 100 cc.

The patient was given ferrous sulfate, 16 gr a day, supplemented with dilute hydrochloric acid and a high vitamin, high-calorie diet. While in the hospital, he was entirely asymptomatic, and showed progressive increase in strength and loss of pallor.

The highest reticulocyte count was 2.8 per cent, but the red cell count and hemoglobin showed a rapid and steady rise until 5 weeks after admission, when the red-cell count was 5,250,000, the hemoglobin 91 per cent, the hematocrit 43 per cent, the mean corpuscular volume 84 cubic microns, the mean corpuscular hemoglobin concentration 27 per cent and the mean corpuscular hemoglobin 22 micromicrograms. After the 1st week the white-cell count rose to levels between 6100 and 13,700. Gastric analysis 4 weeks after admission showed free acid of 8 units and total acid of 56 units, after histamine, the free acid was 18 and the total acid 60 units.

The patient was transferred to the Surgical Service, where three internal and external hemorrhoids were excised, and discharged 6 weeks after admission.

The patient returned to work, taking iron for several

months following discharge. Eight months after discharge, he was entirely well, and the nails had returned to their normal convex contours (Fig. 2). Examination of the blood showed a red-cell count of 5,260,000 with a hemoglobin of 99 per cent, a hematocrit of 46 per cent, a mean corpuscular volume of 88 cubic microns, a mean corpuscular hemoglobin concentration of 33 per cent and a mean corpuscular hemoglobin of 29 micromicrograms, and a white-cell count of 6800.

Comment. The patient gradually developed severe hypochromic anemia coincidentally with koilonychia. On adequate doses of iron, the anemia and koilonychia disappeared, and while taking iron only intermittently, he continued to be well until 6 years later, when anemia and koilonychia again began to develop. Again, these were

first edition of his monograph on diseases of the nails (1900), recorded several additional cases and his original case of a "twenty-five year old, rather chlorotic servant girl," and assigned the name "koilonychia" to the deformity. I have been able to find reports of 83 cases in the literature, in addition to the one reported above.

Idiopathic hypochromic anemia became recognized as a distinct entity after Faber,⁴ in 1913, called attention to the occurrence of a severe type of chlorosis in middle-aged women with gastric acidity. Many subsequent observers have noted

FIGURE 2. Nails of the Patient Fourteen Months after Treatment Had Been Started.

cured by treatment with iron. Hemorrhoids, thought to be the source of chronic blood loss and thus of the iron deficiency, were removed after the second episode of anemia.

DISCUSSION

Koilonychia (*κοίλος*, hollow; *ὄνυξ*, nail) is characterized by an everted distal edge, flat lateral margins, and a spoonlike central concavity of the fingernail. Any number of fingers may be affected and in varying degrees. Associated changes commonly observed are exaggerated longitudinal striations and increased thinness and brittleness of the nails. These changes are also often found in cases of hypochromic anemia lacking typical koilonychia. Flat nails, a less marked phase of koilonychia, have been specially designated "platonychia" by some writers. A case with similar changes in the toenails has been observed by Eddowes (cited by Crocker¹).

The condition was first described by Ball² in 1874, who presented a case to the Society of Biology at Paris, but did not give it a name. Crocker¹ reported another case in 1896, and suggested the name "spoon nails." Heller,³ in the

koilonychia as a frequent but inconstant feature of the disease.

Idiopathic hypochromic anemia (simple achlorhydric anemia, simple achylic anemia, primary hypochromic anemia, achylic chloranemia, chronic chlorosis, chronic microcytic anemia or essential hypochromic anemia) occurs especially but not exclusively in middle-aged women, and is characterized by an insidious onset, long duration, symptoms common to all severe anemias—including paresthesias, but without objective neurologic findings—and, in addition, glossitis and stomatitis. Splenomegaly, koilonychia, cheilitis (fissures at the corners of the mouth) and dysphagia are often present. In the great majority of cases, there is evidence of disturbed gastric secretion (achlorhydria). The anemia is characterized by ready response to adequate iron therapy, and by a tendency to relapse when treatment is discontinued. Careful study often reveals chronic blood loss without adequate iron intake as a cause of the iron deficiency on which the anemia is based. Iron-deficiency anemia has been reviewed by Wintrobe and Beebe,⁵ Heath and Patek⁶ and others.

There are twelve reports,^{1, 7-10} including the present one, comprising a group of 180 cases of idiopathic hypochromic anemia, in which the incidence of koilonychia is stated; it was present in 27 of these cases. In addition, eight observers,^{6, 17-23} reporting a total of 365 cases of idiopathic hypochromic anemia, have noted koilonychia in some of the cases under their observation, but have not specified the number in which it occurred.

Flattening, brittleness and exaggerated longitudinal ridging of the nails may be regarded as important signs in cases of idiopathic hypochromic anemia lacking typical koilonychia. Wintrobe and Beebe⁹ found marked longitudinal ridging or, less often, koilonychia, in 40 per cent of their 25 cases, and McGeorge¹⁰ found brittle, thin and flexible nails in half of his 23 cases as well as koilonychia in 1. Davies,⁸ in a study of 55 cases of hypochromic anemia, found koilonychia in 4, 1 of them a postgastrectomy case, and noted flattening of the nails in 21 and excessive brittleness and tenderness in 31.

Most observers^{7-11, 21-25} have remarked that in cases under their observation in which the anemia was successfully treated with iron, the nail changes disappeared. Walderström and Hallen²⁵ have reported 3 cases of koilonychia without associated anemia, in 2 of which the nails became normal after iron treatment.

The Plummer-Vinson syndrome of anemia, glossitis and dysphagia can probably be regarded as a group of cases having the clinical and hematologic features of idiopathic hypochromic anemia, with dysphagia as a particularly prominent symptom. A large number of cases have been reported, in 27 of which the observers^{12, 24-27} made note of the presence or absence of nail changes. Eight of the 27 patients had frank koilonychia. Ahlbom,²⁸ reviewing 250 cases of carcinoma of the upper gastrointestinal tract, noted frequent appearance of hypochromic anemia, often accompanied by koilonychia.

Faber and his associates²⁰ studied 10 infants, seven to twenty-four months of age, with iron deficiency anemia, none of whom showed koilonychia or glossitis.

A considerable number of other cases of koilonychia have been reported,³⁰⁻⁴⁵ most of them prior to the widespread recognition of idiopathic hypochromic anemia; in a large number of these cases, it was impossible to find a definite causative factor. Several reports,^{2, 30-34} however, suggest strongly that exposure of the hands to chemicals may induce or intensify the condition, whereas other observers^{1, 33-36} have noted a family history of koilonychia, and in a few cases,^{3, 11, 34}

koilonychia was apparently present from early childhood.

SUMMARY

A case of idiopathic hypochromic anemia with koilonychia recurring at a seven-year interval in a middle-aged man is reported. On each occasion, both the anemia and spoon nails disappeared completely on treatment with iron.

A survey of the literature reveals that koilonychia is not uncommonly associated with hypochromic anemia of the iron-deficiency type, and that less marked nail changes, such as flattening, increased thinness or brittleness and exaggerated longitudinal ridging, are common enough to be of diagnostic help in the disease.

MEDICAL PROGRESS

VIRUS PNEUMONIAS. I. PNEUMONIAS ASSOCIATED WITH KNOWN NONBACTERIAL AGENTS: INFLUENZA, PSITTACOSIS AND Q FEVER*

MAXWELL FINLAND, M.D.,† AND JOHN H. DINGLE, M.D.‡

BOSTON

SINCE the introduction of specific antipneumococcal serums, considerable interest has been centered on the etiologic classification of the pneumonias. Before sulfapyridine came into use, however, bacteriologic procedures were employed primarily for the purpose of determining the presence of a pneumococcus and its type, with a view to possible specific serotherapy and perhaps also as an aid in prognosis. The recent sulfonamide drugs that have been widely used—sulfapyridine, sulfathiazole and sulfadiazine—are more or less equally effective against all types of pneumococci. These drugs vary to some extent in their effect on other bacteria, such as streptococci, staphylococci and Friedländer's bacillus, which may be involved in the causation of pneumonia. The determination of the causative organism thus becomes as important as the pneumococcus typing.

The increased use of bacteriologic diagnostic methods in pneumonia and, particularly, the widespread employment of sulfanilamide derivatives have brought into relief a group of cases in which the common respiratory pathogenic organisms do not seem to play a role and on which the sulfonamides do not have the usual favorable effect. Some of these cases have a number of distinctive clinical features, and are thought to be of virus etiology. Moreover, pneumonias are known to occur in certain diseases of nonbacterial etiology—that is, in diseases caused by known filterable viruses or by rickettsias.

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual*, Vol. III, 1942 (Springfield, Illinois: Charles C Thomas Company, 1942. \$5.00).

*From the Thorndike Memorial Laboratory, Second and Fourth (Harvard) Medical Services, Boston City Hospital, and the Department of Medicine and the Department of Bacteriology and Immunology, Harvard Medical School.

†Assistant professor of medicine, Harvard Medical School; associate physician, Thorndike Memorial Laboratory, and chief, Fourth (Harvard) Medical Service, Boston City Hospital.

‡Associate in medicine and instructor in bacteriology and immunology, Harvard Medical School; assistant physician, Thorndike Memorial Laboratory, Boston City Hospital.

This report deals with the various pneumonias considered to be of nonbacterial etiology, and is divided into two parts. In the first, we present a review of the recent studies dealing with nonbacterial pneumonias associated with known virus or rickettsial agents; these include, chiefly, influenza, psittacosis and Q fever. The second part, which will appear in the next issue of the *Journal*, contains a description of atypical pneumonias of unknown etiology, and a review of the attempts to identify a causative agent in such cases.

INFLUENZA AND PNEUMONIA

The occurrence of serious pulmonary complications in cases of epidemic influenza is well known. Such complications are usually considered to be responsible for the high mortality in certain outbreaks of this disease. Whether the pulmonary lesions are caused by the same agent that gives rise to the influenza itself or are the result of secondary invasions with certain pathogenic bacteria was the subject of considerable controversy during the great pandemics of 1890 and 1918. Most workers considered the influenza bacillus of Pfeiffer to be the significant etiologic agent of both the influenza and its complications during the large epidemic of 1889-1890 and in the smaller outbreaks that followed it.¹ The streptococcus, however, was thought by some investigators, notably Finkler,² to be the cause of the severe and fatal influenzal pneumonias of that period.

Similarly, during the 1918 pandemic, although the influenza bacillus of Pfeiffer was found to be the predominant organism in the lungs in fatal cases of influenza in some regions,³⁻⁷ it was conspicuously infrequent in others.^{8,9} In many localities, the hemolytic streptococcus was apparently the predominant pathogenic organism found during this outbreak, and this organism was particularly frequent in the severe and fatal pneu-

monias complicating the influenza that occurred in many of the camps of the United States Army.¹⁰⁻¹⁴ During the same pandemic, there were a few reports of outbreaks in widely separated areas of a characteristic type of pneumonia complicating the influenza in which *Staphylococcus aureus* apparently played the predominant role.¹⁵⁻¹⁷ Occasional similar cases have been noted in other small outbreaks.¹⁸⁻²²

Very similar pathologic lesions were described by a number of different observers during 1918 and were considered, in a general way, to be the characteristic pulmonary lesions of influenza. In some of these cases, the predominant organism recovered from the lungs was the influenza bacillus^{3, 5, 10} in others the hemolytic streptococcus^{11, 23} and in still others the pneumococcus.^{9, 24} Goodpasture²⁵ observed typical histologic lesions in the lungs of 2 patients in this epidemic, but was unable to demonstrate any pathogenic bacteria in the lungs, by cultural methods, in histologic sections or after animal inoculations. Interestingly enough, neither of these 2 cases was of the acute fulminating variety: one patient died on the seventh day, and the other died during an exacerbation of symptoms that had apparently persisted for more than six weeks after the onset of the original influenza.

It is now generally accepted that some filterable virus, identical with or closely related to that originally demonstrated by Smith, Andrewes and Laidlaw²⁶ and later found by Francis,²⁷ was probably the causative agent in most of the widespread epidemics of typical influenza that have occurred in the last few years. This virus has been labeled "influenza A virus."²⁸ Viruses immunologically identical with or very closely related to influenza A virus have been shown by direct isolations or by serologic tests to be the causative agent in the extensive epidemic of 1936-1937^{29, 31} and also in the one that occurred in 1940-1941.²⁹⁻³⁵ In smaller and more localized outbreaks, another virus, now called "influenza B virus," was found to be the cause,³⁶⁻³⁹ and there is indirect evidence that possibly a third one and perhaps still others give rise to the characteristic clinical picture in some limited outbreaks.^{30, 40}

These findings, however, have not entirely clarified the question of the etiology of the pneumonias that accompany the influenzas during outbreaks. There is some evidence^{20, 21} that even cases of simple and apparently uncomplicated influenza may have a spread of the infection to the lungs. The commonest lesion resulting from such an extension, according to Stuart-Harris and his co-workers,²¹ who reported on the 1936-1937 epidemic in England, is a diffuse bronchiolitis,

which may be distinguished by characteristic physical signs and x-ray shadows. They believe that this represents essentially a true virus lesion because of the relative frequency with which virus was isolated from such cases.

Scadding,²⁰ in a study made during the same epidemic, distinguished a group of cases of typical influenza with abnormal physical signs in the lungs, with or without radiologic evidence of consolidation. In the less severe cases of this group, only areas of suppressed breath sounds were made out at the lung bases. In some of the severer cases, the clinical picture was that of edematous lung bases without abnormal x-ray findings, whereas in others there were definite areas of consolidation, both clinically and roentgenographically; only the latter cases were associated with a high mortality. The bacteriologic flora of the sputum in this group was very similar to that of cases without influenza, except that pneumococci were apparently more frequent in the cases with consolidation.

Both Stuart-Harris et al.²¹ and Scadding²⁰ described cases of fulminating pneumonia in which the influenza A virus and *Staph. aureus* were isolated from the same lungs at autopsy; the authors believed that the cases were almost certainly due to both these agents. Stokes and Wolman,²² in 1940, reported a similar case in which both influenza A virus and *Staph. aureus* were isolated from the lungs. In the 1940-1941 epidemic, a number of cases of severe *Staph. aureus* pneumonia complicating clinical influenza were reported from several clinics,⁴¹⁻⁴³ and the relation of the influenza A virus to some of them was presumptively established.^{41, 42} At the Boston City Hospital, *Staph. aureus* was found in almost pure culture or as the predominant organism in all types of cases of influenza, varying from the mild and apparently uncomplicated ones to the fulminating acute and fatal cases with pneumonia, and including a number with a severe and protracted course.⁴⁴ Evidence of infection with influenza A virus was obtained in all the various types of cases,⁴³ either by isolation of the virus or by serologic tests. Interestingly enough, sulfathiazole and sulfadiazine seemed to have a beneficial effect in most of the cases but not in the very fulminating ones. These drugs, however, may have been responsible for the recoveries in some of the very serious cases.

All these findings indicate that under certain circumstances the influenza virus itself may set up a considerable bronchopulmonary reaction, but that in most cases in human beings secondary infection with bacteria plays an important role and

may alter the pathologic picture in the lungs. Analogies are to be found in different animal species.⁴⁵⁻⁴⁹ In the ferret and in the mouse, for example, the virus alone may produce pulmonary lesions almost identical with those found in fatal cases in human beings, and no pathogenic bacteria can be cultivated from the lungs in these animals.⁴⁶⁻⁴⁸ In swine, on the other hand, an influenza virus—either the swine strain or a human A strain—gives rise to a mild infection limited to the upper respiratory tract, and pulmonary lesions in this animal result only from the simultaneous infection with the virus and the swine influenza bacillus.⁴⁹ In the human disease, it appears that both the virulence of the influenza virus and the prevalence and virulence of the co-existing pathogenic bacteria determine the occurrence and severity of the complicating pneumonias.

Furthermore, pneumonias may appear in patients with influenza during the height of the original attack, or they may have their onset after a varying interval, following apparent recovery from the influenza. In the latter event, it may not be possible to obtain the virus when the patient is first seen during the attack of pneumonia, but serologic tests at that time may reveal a high antibody titer characteristic of patients convalescent from the virus infection.^{33, 50, 51} These are evidently relapses of bacterial infection developing in patients recovering from influenza. Typical pneumococcal lobar pneumonia, hemolytic streptococcal or pneumococcal bronchitis or tracheitis and even simple tonsillitis occur under such circumstances.²¹ Francis⁵¹ recovered influenza virus on the second day in a patient with pneumococcus Type 3 pneumonia, and Pearson et al.³³ demonstrated high titers or significant rises in titer of influenza A antibodies in many cases of typical pneumococcal lobar pneumonia occurring during the 1940-1941 epidemic in Boston. Such findings indicate that influenza and other severe pulmonary infections may occur simultaneously, or that such infections may follow shortly after an attack of influenza.

PSITTACOSIS, ORNITHOSIS AND RELATED DISEASES

A human disease, resembling influenza on the one hand and typhoid fever on the other and associated primarily with atypical pulmonary lesions and acquired from sick parrots, has been known since 1880.⁵² Numerous small sporadic outbreaks of such infections, always attributable directly or indirectly to exposure to sick exotic birds, mostly of the psittacine family, were described during the following fifty years. In the years 1929 and 1930, however, there was a pandemic of the dis-

ease, having its origin in an epizootic among imported Brazilian parrots but first reported in human cases in Buenos Aires. It was only after this outbreak had spread through many countries all over the world that the disease, psittacosis, gained considerable prominence. It was during this pandemic that the clinical, epidemiologic and pathological aspects of the disease were clearly recognized and its virus etiology was definitely established. A comprehensive review of the early history of the disease and of the outbreak in England is given in the report of Sturdee and Scott,⁵³ which contains an excellent clinical description of the human disease by Levy-Simpson. This report also contains the classic studies of Bedson and Western, which, together with those of Krumwiede and Armstrong and their associates^{54, 55} in this country, established the filterable-virus etiology of the disease. The virus was found to be associated consistently with minute coccobacillary bodies that are now commonly known as "L.C.L. bodies" after Levinthal,⁵⁶ Coles⁵⁷ and Lillie,⁵⁸ the three workers who described them almost simultaneously in Germany, England and the United States, respectively. These bodies are now generally considered to be the elementary bodies of the virus. Enders⁵⁹ has recently reviewed the various aspects of the disease and the present status of our knowledge concerning the virus that causes it in a symposium on virus and rickettsial diseases at the Harvard School of Public Health. Meyer,⁶⁰ in a recent DeLamar Lecture, presented a comprehensive summary of the biology of the virus and its occurrence in human and avian infections.

There are several reasons for the present intensive interest in psittacosis. First may be mentioned the similarity of this disease to the atypical pneumonias that are now being encountered. In reading the details of the earlier proved cases of psittacosis and the clinical descriptions of that disease that have since been given, one cannot help being impressed with the striking resemblance to the current cases so far as the symptoms, physical signs, roentgenologic and pathological findings and course are concerned. The outstanding differences in the prevalent pneumonias are the failure to obtain a history of exposure to birds, except in certain rare cases that are referred to below; the failure to identify the virus of psittacosis by the usual means^{61, 62}; and the lower mortality. In relation to the mortality, one must consider the lower age incidence of the recently reported cases. Most of the deaths from psittacosis have occurred in persons over forty years of age, and the prevalent pneumonias are uncommon in that age group. Furthermore, secondary pneumonias due to bacterial agents have been men-

tioned in cases of psittacosis, but they have not been encountered in the atypical pneumonias now prevalent.⁶³ This may have accounted for some of the fatalities from psittacosis.

A second reason for the awakened interest in psittacosis is the demonstration of many striking similarities and close antigenic relations between the agent of that disease and a number of other recently discovered viruses.⁶⁴⁻⁷⁰ Some of these new viruses—those of lymphogranuloma venereum, trachoma and inclusion conjunctivitis—have no constant or apparent relation to acute pulmonary infections. Others were isolated from laboratory animals inoculated with materials obtained from patients with atypical pneumonia or with influenzalike infections. Still others, which were discovered as apparently normal inhabitants of the respiratory tract of certain laboratory animals, are capable of inducing pulmonary lesions in those animals under specified experimental conditions.

Interestingly enough, some of these viruses, such as those of lymphogranuloma venereum, trachoma, inclusion blennorrhea and mouse pneumonitis,⁶⁹ are susceptible to chemotherapy with the common sulfonamides, whereas others, including the agents of psittacosis and meningopneumonitis, are apparently not affected.⁷¹ The findings in experimental infections seem to correlate to some extent with published results of sulfonamide therapy in the corresponding clinical conditions. Although sweeping conclusions cannot be drawn from the data thus far available, further investigations of this group of viruses not only may be of theoretical interest but also may uncover new information of value in practical therapy.

Finally, recent studies have indicated a widespread occurrence of psittacosis or psittacosilike viruses in increasing varieties of species of birds all over the world. They have been demonstrated in pigeons living in the wild state⁷²⁻⁷⁴ and in those bred in aviaries,⁶⁰ and have recently been found in pigeons⁷⁵⁻⁸³ and in barnyard fowl.^{82, 83} Evidence for latent infections under these conditions has come either from demonstration of the virus in the tissues or by serologic tests in large numbers of birds. These latent infections may, under suitable conditions, become activated and give rise to spontaneous infections or epizootics among birds, or they may give rise to cases in human beings.⁷⁹⁻⁸¹ Many of the details of these findings have been summarized by Meyer,⁶⁰ who has suggested that the general term "ornithosis" be used to describe the infections in birds or human infections contracted from birds. The designation "psittacosis" would then be reserved for the psittacine infection. The characteristic pulmonary infection might appropriately be called

"ornithotic pneumonia" or "pneumonia ornithosa."

A few of the recently uncovered facts about psittacosis that are of immediate interest may be mentioned briefly. Widespread latent infection has been demonstrated among the common varieties of pigeons and doves, even among those found in the parks of New York City.^{80, 81} Epizootics have been described in many pigeon lofts, and cases in human beings have been traced to this source. The latent infection in pigeons may be activated by dietary deficiency.⁷⁵ Meyer^{82, 83} also reported an epizootic among barnyard fowl in New Jersey. This outbreak, which was associated with human infection, may have originated from a sick dove, which roosted among the chickens shortly before they manifested evidences of infection.

It is remotely possible that certain aspects of this problem may have some significance for armed forces based in far-off lands. Such widely scattered countries as Iceland,⁷⁴ South Africa⁷⁰ and Australia^{72, 73, 84} have figured in the recent reports concerning psittacosis. Viruses very similar to that of psittacosis have been isolated from young fulmars, which are birds of the petrel family living on the cliffs off the Faroe Islands and off Iceland, and they were also found in materials obtained from human patients who had acquired their infection while trapping these young birds for eating purposes.⁷⁴ In several parts of Australia, epizootics have been described in various species of parrots living in the wild state, and dead birds infected with psittacosis have been found in the bush.^{72, 73} Under normal circumstances, the infection of wild birds is usually latent, and is transmitted with difficulty to human beings. From what is already known, however, it is not difficult to imagine situations in which serious human epidemics might arise.

Other Viruses

Other viruses may affect the respiratory tract, although their main clinical manifestations are due to involvement of other systems. In general, the symptoms are those of a grippelike or influenzalike infection. Involvement of the lung to a degree sufficient to give signs by physical or x-ray examinations is rare. The virus of lymphocytic choriomeningitis is an example of such an agent.^{85, 86} In experimental animals, vaccine virus may produce a pneumonia whose pathology is similar to that of the atypical bronchopneumonias in man.^{87, 88}

Rickettsial Infections

The virus of psittacosis and the related viruses are rather large and pass only the coarser bac-

terial filters. They have many morphologic and other characteristics of rickettsias, but no arthropod vectors have been established. Rashes do not occur regularly in psittacosis. These agents have therefore not been classified as rickettsias, although Lillie⁵⁸ had suggested that the psittacosis virus be included among them. They may be said to represent a sort of transitional group between the true filterable viruses and the rickettsias.^{66, 67}

Pulmonary lesions, however, have been recognized as part of the clinical and pathological picture of severe rickettsial diseases, notably in typhus and in Rocky Mountain spotted fever.^{59, 90} In typhus fever, physical signs of extensive pulmonary consolidation are sometimes made out on routine examination of patients who run the usual course, but the appearance of such signs is usually accompanied by an aggravation of the disease and a fatal outcome.⁹⁰ At least in some cases, these pulmonary lesions probably represent infection with the rickettsia and not secondary bacterial infection. Pulmonary complications have recently been reported in cases of South African tick-bite fever,^{91, 92} another of the known rickettsial diseases. Experimentally, characteristic lesions have been produced in the lungs of laboratory animals with several varieties of rickettsias, including the different types of typhus, *fièvre boutonneuse* and Rocky Mountain spotted fever.^{93, 96}

Q FEVER

Like psittacosis, Q fever is of considerable interest at present. The agent of this new disease is quite prevalent in certain parts of Australia and has been isolated and identified in some of the western states in this country. Definite evidence of infection with the agent has been found in this country in certain cases with clinical features closely resembling those of the current atypical bronchopneumonias. The relevant facts about Q fever and its causative agent are therefore briefly reviewed.

Australian Q Fever

In 1937, Derrick⁹⁷ described a new pathologic entity occurring in the state of Queensland, Australia, and gave it the name of "Q fever." Cases, which were first noted early in 1933, increased in frequency in August, 1935. A total of 20 cases had been recognized among 800 employees of one abattoir at the time of the original report, and 9 of the cases were described. Other cases not in meat workers were also noted. Blood and urine from patients, taken during the disease and injected intraperitoneally into guinea pigs,

readily established, after an incubation period of eight to fourteen days, an infection having a definite clinical course and pathological findings and giving rise to specific immunity.

The clinical picture in the human cases was quite characteristic. The incubation period was fifteen days or less. The onset was acute, with malaise, anorexia, headache, pains in the back and limbs, and fever. These symptoms increased in intensity until the patient became drowsy and stuporous, as in the so-called "typhoid state." The temperature was usually sustained at 102 to 104°F., but sometimes was swinging in character, especially in those who had taken antipyretic drugs. Fever lasted from seven to twenty-four days, with recrudescences in some cases. The pulse was relatively slow. Chilly sensations were the rule, but frank chills often occurred. One patient had a punctate rash on the fourteenth day, but this was not considered to be characteristic. Jaundice, conjunctivitis, vomiting, abdominal distention and constipation occurred in some cases. There was a slight cough in 2 cases. The spleen was not palpable, and enlarged lymph nodes were not made out. The leukocyte counts were normal, but a relative lymphocytosis was noted in most of the cases after the fever subsided. Slight albuminuria occurred in all cases, and was sometimes associated with granular casts. No mention was made of pulmonary involvement or of x-ray studies.

Improvement in symptoms occurred gradually as the temperature fell—usually by lysis. Convalescence varied with the length and severity of the illness. General and persistent weakness was frequent, and in individual cases, residual anemia, nervousness ("nerves"), corneal ulcer or thinning of the hair was noted.

The agent isolated by Derrick on guinea-pig inoculation was studied in great detail by Burnet and his associates,⁹⁸⁻¹⁰² who found it to be pathogenic also for monkeys and mice and possibly for rabbits.⁹⁸ Dogs were found to be susceptible but were not considered to play a part in human infection.¹⁰³ With mice, these authors were able to obtain primary isolations from human material by the intraperitoneal inoculation of blood.^{99, 100} In the spleens of infected mice, they⁹⁸ demonstrated typical rickettsia appearing as relatively large intracytoplasmic microcolonies. This rickettsia is fairly large, but is capable of passing a membrane having an average pore diameter of 0.7 micron.⁹⁸ Derrick named it *Rickettsia burneti*.¹⁰⁴ It was found to differ from other rickettsias in that it failed to produce agglutinins for *Proteus* X19 and *Proteus* XK (Weil-Felix reaction) in animals or in man,⁹⁸ and did not give any

cross immunity reactions with other known rickettsias.¹⁰⁵ Like rickettsias, however, it could be grown in tissue cultures but not in bacteriologic mediums.¹⁰¹ Suspensions of this organism were prepared from the spleens of mice and utilized as an antigen that gave specific agglutination reactions with immune serums.⁹⁹ Specific agglutinins appeared in human cases from the twelfth to the fifteenth day after the onset of symptoms, and were also found in animals after infection.⁹⁹

A series of mild and subclinical infections among the laboratory workers was attributed to the handling of infected animals.¹⁰²⁻¹⁰⁶ These infections were usually demonstrated by the development of agglutinins and protective antibodies,¹⁰² but in some cases there was manifest infection and the rickettsias were demonstrated in the blood.¹⁰⁶

Epidemiologic studies revealed a widespread prevalence of the rickettsia of Q fever.¹⁰⁷⁻¹¹³ It was found that the bandicoot, a native rodent of the Australian bush, was susceptible to Q fever, and serologic evidence of latent infection was demonstrated in this species.¹⁰⁷ Later, active infection was proved in these animals by the demonstration of the rickettsia in their blood.¹⁰³ Evidence of latent infection was obtained in other native bush animals, in certain water rats and other native rats, and also in a cow owned by a person who had previously had Q fever.¹¹¹⁻¹¹³

R. burnetii was also obtained from naturally infected ticks collected from bandicoots.¹⁰⁸ It was found possible to infect such ticks experimentally in the larval, nymphal or adult stages by feeding them on infected guinea pigs, and both the latter forms were then capable of transmitting the infection to other guinea pigs.¹¹⁰ There was also suggestive evidence of transoval passage of the agent in the tick.¹¹⁰ The feces of the infected ticks were found to be highly infectious and capable of infecting guinea pigs when applied either to the abraded or the intact skin. It was considered likely that human beings became infected through this method of transmission.¹¹⁰

Surveys among employees of abattoirs in Brisbane and among foresters working 100 miles from the city showed that the infection was quite prevalent among these workers, the infection, however, was usually latent and demonstrable only serologically. No evidence of infection was found among a group of men in a unit of the militia that had had a short period of training in an area where infected ticks were known to be prevalent. This was interpreted as indicating that these ticks probably do not readily infect human beings.¹¹¹ By the middle of 1940,

145 cases, with three deaths, had been studied by the health authorities in Queensland.¹¹³

American Q Fever

In the spring of 1935, Davis and Cox,¹¹⁴ working in the laboratory of the United States Public Health Service at Hamilton, Montana, described a filter-passing agent obtained from a group of ticks of the species *Dermacentor andersoni* that were collected in a nearby place called Nine Mile Creek. Later, three more identical strains were recovered from the same species of tick collected in southeastern Wyoming.¹¹⁵ This agent produced a characteristic febrile infection in guinea pigs, and the agents could then be obtained and transmitted from the blood and urine of the animals. White rats and white mice were also found to be susceptible, but the infection could not be carried beyond the third transfer in rabbits, and monkeys remained afebrile.¹¹⁴

This agent, like *R. burnetii*, was found to survive in and to be transmitted by nymphal and adult ticks that ingested the agent in the larval stage. It also survived through the eggs deposited by infected females, and was transmitted by the progeny.¹¹⁶ It was found to be a gram-negative, pleomorphic, rickettsialike organism that occurred both intracellularly and extracellularly in affected tissues of the guinea pig. It grew well in tissue cultures and in the developing chick embryo, but not in cell free bacterial culture mediums.¹¹⁷⁻¹²¹

One of the members of the staff of the National Institute of Health in Washington, D. C., visited the laboratory in Montana for a few days in May, 1938, and during this time handled infected animals and worked with tissue cultures of the new agent. Ten days after he returned to Washington, he contracted an illness resembling Australian Q fever. The onset was insidious, with pain in the eyeballs, a "tired feeling" and a slowly rising temperature that reached a peak of about 103°F and later dropped gradually. Chilly sensations followed by mild to moderate chills occurred, and later there was a series of drenching sweats for four nights. There were also pruritus in small joints of two fingers, lasting about three days, at the end of the febrile period. The pulse rate was 90 or lower throughout, and the febrile illness lasted about ten days.¹²²

Blood obtained during the height of the fever and inoculated into a guinea pig produced an infection that resulted in the demonstration of an agent identical with the one isolated in Montana.¹²² This agent was then shown to be closely related to the rickettsia of Australian Q fever.¹⁰⁵⁻¹²³⁻¹²⁷ Cox¹²⁵ suggested the name *R.*

diaporica to emphasize its filterability. No pulmonary signs or symptoms were mentioned.

The American disease was tentatively called "Nine Mile fever," but Cox¹²⁶ later considered the name "American Q fever" preferable. Evidence of the occurrence of this infection was obtained by guinea-pig inoculation, by agglutination tests or by both these methods in persons living in seven different states—namely, Idaho, Montana, Wyoming, Nebraska, Oregon, Nevada and Washington.¹²⁶ Bengston¹²⁸ has developed a sensitive complement-fixation test that is specific for the common rickettsial infections and should be of great value both for diagnosis and for the demonstration of immunity.

An outbreak of so-called "pneumonitis" ascribed to the agent of Q fever occurred among employees of the National Institute of Health in Washington, D. C.¹²⁹ Between March 27 and May 17, 1940, 15 cases occurred among 153 employees of one building, and additional similar mild infections occurred in which x-ray studies either were negative or were not done. One of the patients died. An agent identified as the rickettsia of Q fever was isolated from 3 out of 4 proved cases of pneumonitis, including the fatal case.¹³⁰ Specific agglutinins for the Montana strain and for a strain isolated during the epidemic were found in 9 of 12 proved cases and in 1 of 2 suspected cases. No positive tests were obtained in control serums from workers either in the rickettsia unit or in other units, but a few doubtful results were obtained among the former. Specific neutralizing and complement-fixing antibodies also developed in these cases.^{128, 130} There was no valid evidence that person-to-person contact or the intervention of an arthropod vector was responsible for the transmission of the disease. Although strains of Q fever had been carried in animals and tissue cultures in one unit of the institute since 1938, the personnel of that unit was spared, and the cases were widely distributed throughout the building.

The clinical features and the physical and x-ray findings in these cases were very similar to those of the various atypical pneumonias currently reported from various parts of the United States. The onset was either coryzalike or with headache, chilly sensations and malaise. There was a latent period of three days after the onset, during which headache was severe and constant, but the patients continued to work. In 1 case, there was a dramatic onset, with abdominal cramps, chills, fever and headache while the patient was at work. Chills, fever, sweats, and pains and aches were frequent. Nausea and vomiting occurred in 3 cases. Several patients developed a hacking cough, which in a few cases was productive of thick,

tenacious white mucus, but not "prune juice" or "blood-tinged" sputum. About half the patients had a vague neuralgic type of chest pain that was either substernal or on the side of the lung lesion, but was not pleuritic. All complained of insomnia.

The paucity of physical signs was characteristic. There was no evidence of respiratory embarrassment or any other obvious indication of pneumonia. In some cases, there were areas of dullness or increased breath sounds, or infrequent sticky rales were heard. The pulmonary lesion probably would not have been discovered in most cases except for the x-ray picture. This was the most typical and consistent evidence of the pneumonia. It showed soft, infiltrating lesions, either single or multiple, that were not uniform as in lobar pneumonia but tended to be patchy.¹²⁹

The histopathology in the lungs of the fatal case¹³¹ closely resembled that described by Kneeland and Smetana⁶³ and by Longcope.¹³² Rickettsias were not seen. The spleen showed a picture similar to that found in experimentally infected monkeys¹³¹ and resembled that described in Kneeland and Smetana's⁶³ case. Lesions in the lungs similar to those found in the human case were also described in experimentally infected guinea pigs¹³³ and mice.^{134, 135}

Two similar cases of American Q fever have been reported from Montana.¹³⁶ One patient had typical pneumonitis. Both cases were proved by agglutination tests, and the causative agent was isolated in 1. These infections occurred in the late fall, and both patients had been out in the woods before the onset of symptoms. There was no history of tick bite in these cases, nor was this likely at that time of the year.

Comparative studies of the American strains of *R. diaporica* and the Australian strains of *R. burneti* have been made in both countries and have given fairly uniform results.^{105, 122-124} Immunologically, these strains are indistinguishable. Such differences in pathogenicity as have been noted may be ascribed to the lower virulence of the Australian strains, which has been fairly constant according to all the experimental work.

The clinical differences between the Australian and the American disease have already been commented on in the *Journal*.¹³⁷ Outstanding is the fact that pulmonary involvement or suggestive symptoms of such involvement have not been mentioned in the Australian cases. This may, of course, be due to the lower virulence of the infecting agent in Australia. It is also possible that such lesions have been recognized more easily in this country because of the readiness with which x-ray films of the lungs are made here, particu-

larly in the classes of patients in whom the reported cases have occurred.

The exact place of Q fever in relation to the etiology of the prevalent atypical pneumonias is not yet clear. Except as already noted, no group of proved cases of pneumonia due to this agent has been reported, although many have searched for it. These rickettsias, like the agents of the psittacosis group, may account for only a small percentage of the cases.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28351

PRESENTATION OF CASE

A fifty-year-old woman was admitted to the hospital because of persistent crampy abdominal pain.

Approximately a week before admission, she became constipated and accordingly took a laxative. After this, she developed generalized crampy abdominal pain, which persisted to the time of admission in spite of repeated enemas. These were productive of small stools and great amounts of flatus. There was no vomiting, and no melena or fresh blood in the stools.

The past history was irrelevant, except that the patient has always been somewhat constipated, requiring the frequent use of mild cathartics. Also, for several years she had had slight, irregular metrorrhagia. Her husband stated that for several years she had complained of mild abdominal aches and pains. She ascribed these pains to the onset of menopause, although she was still menstruating. She had been married for thirty-one years and had had four children.

Physical examination revealed a well-developed and well-nourished woman in no acute distress. Examination of the lungs and heart was negative. The abdomen was markedly distended and tympanic. Peristalsis was moderately high pitched but not tinkling. Rectal examination was negative.

The blood pressure was 140 systolic, 70 diastolic. The temperature was 99°F., the pulse 80, and the respirations 20.

Examination of the blood revealed a red-cell count of 4,040,000 with a hemoglobin of 12.4 gm., and a white-cell count of 17,400. The blood Hinton reaction was negative. The nonprotein nitrogen was 24 mg. and the protein 6.1 gm. per 100 cc. The urine examination revealed a specific gravity of 1.026 and a ++ test for albumin, and the sediment contained 200 red blood cells and 15 epithelial cells per high-power field.

A flat plate of the abdomen demonstrated that the colon and small bowel were markedly distended with gas. Most of the gas appeared to be within the colon and extended to the region of the sigmoid.

A proctoscopic examination was performed. The proctoscope was passed 18 cm., where on the

left anterior wall of the sigmoid, just below the level of the cervix, a localized mass was visualized. Biopsy, performed with difficulty because of pressure from a large heavy cervix, was reported as showing acute and chronic inflammation. A biopsy of the cervix showed chronic endocervicitis. During a barium enema, the barium passed very slowly through the terminal 5 cm. of the sigmoid. The lumen of the bowel was considerably reduced, and frequently went into spasm. No definite filling defects or ulcerations were seen. A second proctoscopic examination was performed. The scope passed 18 cm., but further progress was impossible because of inflexibility of the sigmoid due to an extrinsic mass. A good view of the recto-sigmoid was obtained, and no break was found in the mucosa so far as it was exposed. The tumor mass seemed to lie anteriorly and did not involve the cervix.

On the fifth hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK: I think perhaps we had better see the x-ray films before starting this discussion.

DR. AUBREY O. HAMPTON: This is the first film, which demonstrates obstruction in the colon. The gas extends down to the sigmoid. The small bowel is more dilated than is usual with a lesion as low as that; it is, nevertheless, only moderately dilated, whereas the colon is markedly so. I am rather surprised that they said this area did not represent a filling defect. I should call it an annular constriction, with a definite filling defect. I do not see the evidence of spasm. That was perhaps observed at fluoroscopy.

DR. MCKITTRICK: This whole picture, to me at least, is difficult to put together logically. The history is short, with a rather sudden onset, and yet the patient came in markedly obstructed, which is unusual, it seems to me, for so short a story. We might try to connect the obstruction in the large bowel with the abdominal aches and pains that she is said to have complained of for several years, but they were quite indefinite, and I do not see how we can put much significance on them.

Metrorrhagia is mentioned, but no vaginal examination is recorded, and I cannot believe the patient did not have an examination.

DR. TRACY B. MALLORY: She had one under anesthesia, and a biopsy of the cervix was done. Evidently the findings were not remarkable.

DR. MCKITTRICK: That is all right. It would be nice to know if she were staining.

There were 200 red blood cells in the urine. How shall I explain that? It seems to me difficult to make all these things fit what I believe is the correct diagnosis.

On the basis of what we know, the patient had something obstructing the sigmoid. She might have had an infiltrating process on the outside that was constricting it, some process within the wall of the bowel itself that narrowed it down, or something within the lumen that caused the obstruction. This woman had had pain for some time, and the abnormal menstrual history makes one wonder if she had an endometriosis that was responsible for the obstruction and menstrual disturbance. I cannot make such a diagnosis with certainty and shall dismiss it. The next possibility is a malignant process in the pelvis, originating in the uterus or ovaries, which had actually extended to the point where it had shut off the bowel. I do not believe it is logical to assume that this occurred.

Then there is regional enteritis or a localized area of ulcerative colitis. These are remote possibilities. A local amebic ulceration, a so-called "amebic granuloma," might be considered, but I do not know how to make such a diagnosis. Diverticulitis should be mentioned, but I do not believe that process would give this picture on proctoscopic examination. Although the x-ray film is often not too accurate at the level of this lesion, it seems quite definite in this case. Sigmoidoscopic examination, too, is sometimes very difficult at this level, particularly if there is fixation of the bowel from something either within or outside the bowel. It would help us greatly in our interpretation if we could be sure—as the examiner stated—that the mass was extrinsic. I do not believe that the pathological report of "chronic inflammation" means anything. We have failed at times to get our specimen from the right place. I must end up by putting my money on the horse that usually wins the race: I must say carcinoma of the rectosigmoid because I do not know what other diagnosis to make. I have not been told anything about the 200 red cells. I do not know what they were doing there, and I shall not make any attempt to explain them.

DR. MALLORY: This patient was operated on because of the severe degree of obstruction. At the first operation, nothing was done but a tube cecostomy, and the bowel was put at rest for nearly two weeks. Then a second operation was done. This time, a fairly thorough exploration revealed a large tumor mass in the region of the rectosigmoid, somewhat adherent to the uterus but movable enough so that it could be resected. It was still considered unwise to attempt a resection at the moment because the bowel contained such large amounts of fluid feces that it seemed

risky. On this occasion, a colostomy was done.

Would any of that information lead you to change your mind?

DR. MCKITTRICK: No, but I suppose you are going to tell me that this was all inflammatory and when the patient came back for operation they did not find anything.

DR. MALLORY: Not so bad as that.

CLINICAL DIAGNOSIS

Carcinoma of rectosigmoid.

DR. MCKITTRICK'S DIAGNOSIS

Carcinoma of rectosigmoid.

ANATOMICAL DIAGNOSES

Endometriosis of uterus and sigmoid.
Intestinal obstruction.

PATHOLOGICAL DISCUSSION

DR. MALLORY: At the final operation, the large tumor mass was again found to involve both the sigmoid and the uterus. For that reason, hysterectomy was first performed, followed by an abdominoperineal resection of the sigmoid and rectum. It was necessary to remove a segment of the posterior vaginal wall as well. When we opened the sigmoid, we found that it contained two intramural tumors that projected into the lumen, separated from each other by 2.5 to 3.0 cm. The mucosa over each tumor was perfectly smooth and nowhere ulcerated. The muscularis was markedly thickened, and one could see very clearly the transverse strands of the muscularis running through the tumor—in other words, there was infiltration of the bowel wall without destruction of the musculature. In several places, there were tiny cystic cavities containing blood. On the posterior surface of the uterus were some firm white nodules looking like tumor implants. On section, each of these nodules contained chocolate fluid, confirming the diagnosis of endometriosis. We have seen endometriosis invade and obstruct the sigmoid before, but I do not believe we have ever seen endometriosis so extensive as this in a woman of fifty. She was still menstruating, however.

CASE 28352

PRESENTATION OF CASE

An eighteen-year-old schoolboy was admitted to the hospital because of a mass in the right thigh.

About three and a half months before entry, the patient was kicked in the thigh while playing football. The resultant slight swelling and stiffness without discoloration lasted only a few days. The injury was then forgotten until a month later,

when the patient noted a firm swelling, somewhat larger than a golf ball, at the site of the former trauma. Following its discovery, this mass grew rapidly. At no time was this lump painful, hot, discolored, numb or throbbing. A month before entry, the patient consulted a physician and was told that he had a "broken blood vessel." There was no loss of weight or fever.

The past and family histories were irrelevant.

On admission, abnormal physical findings were limited to the right lower extremity. In the anteromedial portion of the midthigh was a firm solid rounded mass 10 cm. in diameter. It was not tender, and could be moved by the examiner or by the patient along with the quadriceps muscles.

The pulse, temperature and respirations were normal.

Examination of the blood showed a white-cell count of 7400 and 100 per cent hemoglobin. The blood calcium was 11.3 mg. and the phosphorus 3.8 mg. per 100 cc., and the phosphatase was 4.2 Bodansky units. The blood Hinton reaction was negative. The urine was normal.

A roentgenogram of the right thigh showed a soft-tissue swelling in the anteromedial aspect of the middle third, with linear areas of calcification within the swollen area. This calcification did not run in the direction of the muscle fibers. A roentgenogram of the chest showed a ring shadow in the right apex, probably an artefact. The lung fields were otherwise clear. The heart seemed normal.

On the third hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CARROLL B. LARSON: The history leads one to think first of all and most strongly of myositis ossificans. A definite injury, severe enough to result in a hematoma, partially subsided, only to be followed by the appearance of another mass at the same site. This places the lesion on a traumatic basis, and it is well known that trauma initiates osteogenesis, although the mechanism of this process is obscure. The location of the mass is one of the three sites of predilection for the occurrence of osteogenesis following trauma—the other two being in the upper extremity about the deltoid muscle and near the attachment of the triceps muscle. Someone has accounted for aberrant osteogenesis in the abdominal wall on the basis of an embryologic rib remnant, which I am sure does not account for osteogenesis in the thigh. The x-ray films show an area of calcification inside the solid tumor that is globular, well defined and completely separate from the femur. The calcification is generalized, with a sprinkling of more localized calcium deposits, so that it has a dotted-

veil appearance that is quite characteristic of myositis ossificans. I do not see that the calcification here follows any definite pattern or direction. An ordinary calcified hematoma gives a different picture and tends to follow fascial planes, for which this mass has no regard, so that I believe we can rule out hematoma.

Malignant tumors must definitely be considered. These might be primary or might originate in a focus of myositis ossificans. In a series of 25 cases of the latter, 1 definitely malignant case was encountered. This is reasonable, when one considers that the elements of normal bone are present in the bone formed in myositis ossificans, which is therefore subject to the changes of any bone, that is, osteogenic sarcoma, fibrosarcoma, parathyroid changes and so forth. It has been a clinical observation that a diagnosis of malignant tumor in myositis ossificans is difficult, and occasionally must be based on the subsequent course rather than on the microscopic appearance.

I doubt whether we can tell from the history, x-ray films or physical examination whether this mass was malignant; the final diagnosis depends on the histologic structure of the tumor and the future clinical course.

DR. LAURENCE L. ROBBINS: Dr. Larson has pointed out the mass and the calcification. I am sure I cannot tell whether this calcification goes with or against the muscle fibers. One thing that is of some importance, at least so far as the history is concerned, is the fact that in the work done at Dillon Field House, Harvard University, the calcification in cases of myositis ossificans usually appeared within three weeks, and increased from that time on. Judging from these observations, there should be a great deal more calcification in this case than there is, if it was myositis ossificans.

DR. ERNEST M. DALAND: I should like to say that when we pinned this boy down to a more definite history he said that he had been in a football game but was not certain that this was the point where he had been injured. Certainly, there was no hematoma or ecchymosis.

DR. LARSON: I do not believe that rules out myositis ossificans, because in the largest series that I was able to find only 50 per cent of the patients gave a history of injury.

DR. TRACY B. MALLORY: The chief question in a case of this sort, in which it is obviously impossible to make an accurate preoperative diagnosis, is, What would one do about it?

DR. LARSON: I should like to know one more thing, not recorded in the history: Was there any pulsation or any bruit?

DR. MALLORY: No; there was not.

DR. LARSON: In a case like this, hemangioma is perfectly possible but I do not think it likely;

outside the United States, and the participation of South American and Central American physicians in the proceedings contributed greatly to the international character of the meeting. In addition, the presence in the *Journal of the American Medical Association* of a larger number of abstracts of papers appearing in the medical periodicals of these other countries indicates a growing appreciation of medical matters of mutual interest, and a sanitary-engineering survey of South America now under way will undoubtedly lead to further co-operation. Such an interchange of medical thought will undoubtedly contribute much to medical advance.

MEDICAL EPONYM

RAYNAUD'S DISEASE

A. G. Maurice Raynaud (1834-1881) described this disease in a thesis submitted to the Faculty of Medicine in 1862 and entitled *De l'asphyxie locale et de la gangrène symétrique des extrémités* [*Local Asphyxia and Symmetrical Gangrene of the Extremities*] (Paris, 1862: 174 pp.). A portion of the translation follows:

I propose to demonstrate the existence of a kind of dry gangrene affecting the extremities, which it is impossible to explain by vascular obliteration; a kind that is characterized particularly by a remarkable tendency to symmetry, in that it always affects similar parts, the two upper or lower extremities, or all four at once; furthermore, in some cases, the nose and the ears are affected, and I shall endeavor to prove that this species of gangrene is caused by a disorder in the innervation of the capillaries. . . .

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY COMMITTEE ON MATERNAL WELFARE

CASE REPORT: OPERATIVE DELIVERY FOLLOWED BY SHOCK AND DEATH

A thirty-six-year-old para III was sent to the hospital. The past history was entirely irrelevant. The two previous pregnancies had terminated normally with living children. The labor of the third pregnancy was long, and after two hours of strong second-stage pains, forceps delivery was attempted at home but was unsuccessful. On admission, the patient was given ether, and a difficult midforceps extraction was accomplished. A living child was obtained. Immediately after delivery, the pulse became very rapid, although

there was no unusual bleeding. The patient was not transfused, but intravenous glucose and stimulants were administered. Death occurred one hour after delivery. An autopsy was not performed, and the death certificate was signed "organic heart disease and cardiac decompensation."

Comment: Since there is nothing in the past history of this patient to suggest organic heart disease and cardiac decompensation, and since no autopsy was performed to confirm this diagnosis, it seems much more probable that death was caused by post-partum shock. In all probability, this fatality was due solely to poor obstetrics. The delivery in the hospital was described as "difficult"; nevertheless, it was successful, and a living child was obtained. It is fair to conclude that had this patient been hospitalized at the beginning of labor, the same operation would not have been difficult several hours earlier, and that shock and death would not have resulted.

DEATH

HOGAN — DANIEL J. HOGAN, M.D., of Roslindale, died August 15. He was in his fifty-sixth year.

Dr. Hogan received his degree from Tufts College Medical School in 1920. He was a major in the United States Army Medical Corps, and a member of the Massachusetts Medical Society and the American Medical Association.

His widow survives him.

WAR ACTIVITIES CIVILIAN DEFENSE

INSTRUCTIONAL FILMS

An excellent sound film, "Emergency Medical Service," is now available for medical units. It shows how an emergency medical service operates in co-operation with the other civilian-defense services, and the accompanying sound disk explains clearly the operations of the unit. The showing time is twenty-one minutes.

This film and other very good instructional 16-mm. sound and silent films on first aid, chemical warfare and first aid for gas casualties are available through the Film Department, Speakers' Bureau, Massachusetts Committee on Public Safety, 18 Tremont Street, Boston. These films are loaned to any medical unit that specifies the date on which the films are desired, guarantees the cost of shipment and provides suitable equipment and the services of a competent operator.

MISCELLANY

RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR JULY, 1942

DISEASES	JULY 1942	JULY 1941	FIVE-YEAR AVERAGE
Anterior poliomyelitis	8	5	9
Chicken pox	436	519	421
Diphtheria	22	9	13
Dog bite	1276	1286	1228
Dysentery, bacillary	0	24	30
German measles	211	116	56

infections Therefore, it is probably allergic rather than viral in origin In acute encephalomyelitis, the onset is abrupt, and the involvement widespread The patients either succumb or recover only to have some residuum In the latter event, the disease is often diagnosed as multiple sclerosis But the onset of the latter disease is usually less widespread, and one group of symptoms and signs disappears as others occur There seems no evidence of a virus etiology for this syndrome

In conclusion, Dr Merritt pointed out that, from 1928 to 1938 at the Boston City Hospital, 1 in 3680 admissions and 1 in 126 neurologic admissions were for encephalitis

Dr Thomas then discussed some of the investigative problems The equine and St Louis encephalitudes, although caused by different viruses, may merge during epidemics At present, there is no way of determining whether these diseases will continue to increase in incidence or disappear, as the Australian X disease did But whereas equine encephalitis was originally considered solely animal, it and louping ill have become human and may be forerunners of other animal diseases now studied in the laboratory The classification of virus diseases of the nervous system cannot be based on histologic findings because of their lack of specificity and consistency Attempts have been made to class them as epidemic and nonepidemic, neurotropic and pantropic, and according to whether their virus etiology is proved, probable or suspected

Laboratory detection of a virus is difficult, and identification is usually dependent on immune reactions This may be carried out by injection of the unknown material into animals vaccinated against known viruses, by neutralization of the injected material with various antisera before injection and by some newer *in vitro* methods

Dr Thomas then considered the epidemiology and immunology of specific diseases St Louis encephalitis has been increasing geographically since the first epidemic in 1933, and is often associated with Western equine encephalitis The virus can be isolated only from the central nervous system in fatal cases, but immunization may be carried out by nasal irrigation in known cases or in infected animals These late summer epidemics are most costly to borne and have their perpetuation in stagnant water Horses have shown evidence of previous attacks in immune reactions Antibodies appear in two weeks and persist indefinitely The virus must be identified in the blood and cerebrospinal fluid for its etiologic role to be proved

Western equine encephalitis has been increasing in man each summer since 1937 This virus has been isolated from the blood and cerebrospinal fluid in active cases, as well as from post mortem material Its presence in ticks, as well as in many animals, birds and mosquitoes, may explain some dry season epidemics Neutralizing antibodies are found early, whereas complement fixing ones may persist for three years

Eastern equine encephalitis, known in horses since 1933 and in man since 1938, is immunologically distinct from the Western variety but is transmitted similarly Its virus has been isolated only from autopsied central nervous system tissue Neutralizing antibodies have been demonstrated as early as six to eight days

Other forms of encephalitis are of less practical importance Australian X disease may be the same or similar to louping ill, but its virus has been lost and the disease seems extinct Japanese B encephalitis is apparently very similar to the St. Louis type in manifestations and epidemiology

Russian forest spring fever is carried by a rodent-tick combination Louping ill, transmitted by a sheep tick, has caused rare cases in laboratory workers The B virus of the monkey may be responsible for a rare case of fatal ascending myelitis Lymphocytic choriomeningitis occurs naturally in mice, in which the manifestations, however, are nonspecific It can be transferred *in utero* Transmission to human beings can often be traced to recent handling of mice, and even home rodents are not above suspicion as carriers The virus apparently may enter the intact skin Insect transmission is possible but of no practical significance as yet

Von Economo's disease has always been clinically suspected of having a virus etiology, but none of the present known strains have been identified Similarly, infectious polyneuritis and herpes zoster are considered to be viral in nature, but the responsible agent still escapes detection

Dr Henry R Viets opened the discussion by pointing out that there may be multiple invasions by viruses Strong antibody titers may be observed for as long as seven years Dr Conrad Wesselhoef stated that one virus activating another may be the mechanism behind certain postinfectious encephalitudes Of 4 patients who developed encephalitis during the third week of measles, 3 were found to have the virus of the Eastern equine strain Post measles encephalitis is not uncommon, but there are surprisingly few personality changes in relation to the amount of coma accompanying the attack In mumps, encephalitis may be concurrent or even imitating, as well as occurring during convalescence In the former event, it is often difficult to rule out the diagnosis of paralytic poliomyelitis As many as 800 leukocytes per cubic millimeter may be found even in routine spinal fluids from patients with mumps, which leads to the suggestion that this is really a systemic disease

BOSTON CITY HOSPITAL

The first of a series of lectures sponsored by the Boston City Hospital House Officers' Association as a preparation for physicians entering the armed forces was given on May 5 at the hospital

Dr Donald W MacCollum spoke on 'The Practical Management of Burns' He first considered thermal burns First-aid instruction for the layman should emphasize the care of shock in any burn If a physician is not present but available, the burned area should be covered with clean linen In minor burns, the patient may be taken to a first aid post, but in the more extensive cases the doctor should be brought to the patient Tannic acid ointment should not be applied to any burn at this stage If a physician is not available for several hours, minor burns should be washed under running water, if that is available, and should otherwise be covered with a paste of sodium bicarbonate and water The area is then loosely wrapped with an abundant clean bandage, and the patient is sent to a doctor For extensive areas, easily removed clothing is gently removed without further attempts at cleansing, the patient is covered with clean clothes soaked in a warm solution of sodium bicarbonate, kept warm, given tea or coffee by mouth and hurried to a hospital The important points to be remembered are tannic acid jelly or strong tea should not be applied to a burn before it has been properly cleaned, grease in any form should be avoided, the patient should not be manipulated unnecessarily in an attempt to apply a neat bandage

First-aid instructions to physicians emphasize the value of examining and treating the patient for actual or in

ipient shock before the burn is cared for. For this purpose, the control of pain with adequate amounts of morphine is very necessary, and the dose should be double that usually administered before an elective operation on a patient in shock. In severe shock, oxygen by some method, intramuscular caffeine and plasma, if available, should be given. The last is administered intravenously at the rate of 5 cc. per pound of body weight. In its absence, physiologic saline solution, 10 cc. per pound, may be temporarily given. Only after shock has been combated should the burn be evaluated. If the burn is minor, cleansing is carried out by gentle washing for seven minutes with sponges soaked in 50 per cent solution of green soap (not tincture) and 50 per cent hydrogen peroxide. Débridement is done only with sterile instruments, and the area is then flushed with copious amounts of physiologic saline solution or distilled water, dabbed dry, and dusted with one of the sulfonamide powders. Burns of the hands, feet, face and genitalia are covered with a sterile ointment and bandaged as well as possible. Elsewhere, tannic acid jelly or triple dye may be employed. Splinting should be carried out wherever indicated for the best orthopedic results. In the event of a major burn, only the adherent clothing and the gross contamination, without extensive cleansing, are removed. One of the sulfonamide powders or an emulsion or suspension in a water-soluble base is then liberally applied. If powders are used, they should be covered preferably with a water-soluble jelly, since they are more easily removed than the sterile ointments and triple-dye jelly, which, however, may be used. Thick bandages, to prevent soaking through and further contamination, are applied, with a surrounding pressure bandage if possible, and the victim is hurried to a hospital. The major points in this group are: the shock should be treated before all else; tannic acid ointment should be applied only after the area has been cleansed, and never to the hands, face, feet and genitalia; adequate doses of morphine should be used; the sulfonamide powders should not be allowed to enter the nose and eyes, where they are very irritating; and a very thick bandage should always be applied over extensively burned areas.

Hospital treatment of burns of minor degree is essentially that described above under first-aid treatment by physicians. In major burns, the degree of shock should be checked clinically, and further treatment in the form of heat, morphine and so forth should be administered. If time permits and facilities are available, determinations of the red-cell count, hemoglobin, hematocrit and serum protein are helpful but not necessary. Additional plasma in the amounts recommended above should be given. Whole blood should not be used except when there has been blood loss from other injuries. Anesthesia is employed if indicated, the intravenous or rectal route being chosen if there is any question of hot air or gas inhalation. The area is cleaned and débrided as described above, under sterile precautions. Burns of the hands, feet, face and genitalia are dusted with one of the sulfonamide powders, covered with a sterile ointment and bound with thick layers of gauze, and the extremities are splinted. For burns elsewhere, a similar routine may be carried out only if one is prepared to combat the fluid loss with repeated plasma transfusions. Usually, it is better to employ one of the escharotics to prevent serum loss, but specialized aftercare is probably one of the more essential features of this type of burn. This includes a clean, electrically heated bed, frequent evaluation of the blood chemistry, adequate oral and parenteral fluid intake, and constant medical and nursing care.

The hospital treatment of old burns differs in certain respects from that outlined above. The use of the sulfonamides in the first-aid treatment increases the period during which débridement may be carried out to as long as thirty hours after the burn has been received. Otherwise, this procedure is contraindicated later than eight hours, since the area should be considered already infected. Shock treatment is still the first consideration. The patient is then immersed in a tub of warm tap water, with constant exchange of water for several hours. After gentle drying, the sulfonamide powder of choice is used and is followed by a sterile ointment. Tannic acid in any form is contraindicated. If the burn is crusted, the area may be first covered with what some consider the dressing of choice in old burns, namely, wet saline or *tulle gras* with Eusol—a chlorinate compound made of slaked lime and sodium bicarbonate.

Grafting should not be necessary in second-degree burns, and in deeper ones the kind and amount of graft depend on the extent and site of the burn. Special preoperative precautions are taken to have the patient in the best possible condition generally and locally. The important conditions for successful results are to have the granulations cleaned at least to their fibrous base, which in cases of contractures should be removed. Island or Reverdin grafts should be strictly avoided for the best cosmetic results and for the shortest convalescence.

The second large group of burns are those caused by chemicals. The first warning here is for the attendant to protect himself. Mustard gas is really a fine oily vapor, and the exposed areas must be attacked early. All clothes are removed and decontaminated. Then, the victim is given a thorough soap-and-water scrub, followed by shaving of hairy regions if they have been affected, for they are not otherwise easily cleaned and may develop subsequent burns. If this is done in less than a few hours, there is no need for further treatment, but the patient should be observed temporarily. In patients seen after eight hours, the burned areas are treated like any old burn. One should always consider the possibility of damage to the pulmonary structures if anesthesia is contemplated, and morphine for shock should be avoided for this same reason.

Treatment of exposure to lewisite liquid is of no value after one minute. Within that time, the area should be bared of all covering, and the wound repeatedly swabbed with hydrogen peroxide, which is continued for half an hour. The area is then washed for seven minutes with soap and water, and an alcohol pad is applied and left in place for five minutes. A dry dressing is applied, and if no blister appears in twelve hours, the patient may be discharged. If blisters develop, they are then treated carefully, so that none of the fluid escapes onto the surrounding skin, for it contains the same arsenical as the original fluid and will cause grave injury. Even a small amount of this material will be fatal if it reaches the blood stream through any route. If blisters have broken and the patient shows signs of arsenical poisoning, the entire area is widely excised, and immediate graft carried out. Sodium thiosulfate is the drug of choice in combating systemic poisoning.

Phosphorus has the peculiar property of continuing to burn even after being imbedded in the flesh. If there is none still active, the area may be treated as a thermal burn. But if bits of the material are smoldering on or in the skin, the region must be kept wet, preferably with warm water. Five to 15 per cent copper sulfate may be applied if available, for it will temporarily stop the burn-

ing But the phosphorus particles must be removed by some method before the patient can be considered out of danger Thereafter, the treatment is the same as that for any burn

Acids and alkalis, contrary to popular belief, should not be neutralized, for in that way the heat generated or the neutralizing agent may cause a burn It is preferable to use continuous running water or to immerse the victim in a tank or nearby body of water The only exception to this is that excess lime is wiped off before wetting

Electrical burns are deceptive from the first One should not be overzealous in attempting to remove a patient from the scene before first determining that the current has been disconnected or that the rescuer is properly insulated The patient should not be regarded as dead until rigor mortis sets in, for several cases are reported of recoveries after many hours without a perceptible heart beat Almost all these burns are third degree or more because of the intense heat and coagulation of the blood in the vessels supplying the area Coagulation may cause slough on the seventh to tenth days, sometimes with hemorrhage The area is treated like any burn except that no eschars are applied, and daily dressings are done to follow the progress of the slough if there is any Sloughed areas are not surgically removed but are allowed to separate for the amount of tissue thus lost is much less than would have been computed at an earlier stage Sterile hemostats and a tourniquet should always be at the bedside, to guard against the danger of hemorrhage at the time of separation of the slough

BOOK REVIEWS

Allergy in Clinical Practice By staff members of the Cleveland Clinic Under the direction of Russell L Haden, M.D., chief of the Medical Division Edited by J Warrick Thomas, M.D., chief of the Section on Allergy 8", cloth, 370 pp, with 92 illustrations, including 14 in color Philadelphia J B Lippincott Company, 1941 \$5.00

This book is an endeavor to present the various phases of allergy as applied to general practice The well known manifestations of allergy with reference to the upper and lower respiratory systems and skin receive major emphasis, with some consideration of the less common reactions on the gastrointestinal, ocular and endocrine systems The presentation is orderly and marked by clarity and brevity In fact, if what appears to be a disproportionately large number of illustrative case reports were considerably reduced, one would be left with a concise monograph summarizing the general principles of allergy without appreciable loss of practical value

The Advancing Front of Medicine By George W Gray, AB 8", cloth, 425 pp New York Whittlesey House 1941 \$3.00

It is a task of no little difficulty to present matters of scientific research to the public so that they are readily understandable, to convey the facts with accuracy and the significance of those facts with clarity But Mr Gray has achieved it here with almost astonishing perfection He has done it, moreover, without resorting to the false sensationalism that so often offends in similar pieces of reporting And the more, because he is an outsider looking in, does one marvel at his restraint and judgment

But Mr Gray's front' should really be fronts He has chapters on the nature of disease, on heredity, on the vitamins (on which the public has been so perniciously exploited), on the blood and its disorders, on hypertension, on the sulfonamide drugs, on influenza, on allergy, on the relation of anxiety to health, on epilepsy and certain other nervous disorders, on sleep, on pain and its relief, on drinking, smoking and drug addiction, on cancer and on growing old

With its wide range, its sane way of weighing and balancing and its bits of history, this book is revealing even to a physician, how much more so, then, to the layman, to whom nearly all its matters must come as something fresh and new Perhaps its selection by the Scientific Book Club will increase its circulation, it deserves a wide one, for it is capable of doing a great deal of good

Diseases of Women By Harry S Crossen, M.D., and Robert J Crossen, M.D Ninth edition, entirely revised and reset 4", cloth, 962 pp, with 1127 engravings, including 45 in color St Louis The C V Mosby Company, 1941 \$12.50

This is the ninth edition of a very familiar textbook on diseases of women The greatest advances that it heralds are those of endocrinology and chemotherapy The former has imposed on the whole field of gynecology a physiologic approach in place of the anatomic and pathologic As a result, one gets a picture of a changing and cyclic rather than a static group of organs The adaptation of the newer hormonology to clinical use has been well treated by the authors There is a scarcity of information about subfetol, which might well be explained by the rather recent release of this drug by the Council of Pharmacy and Chemistry of the American Medical Association

This is not an operative book, but rather a treatise on diagnosis and therapy Preparation for operation and postoperative care are discussed, but the technique of surgical steps is not included Because of the scope of this work, one hesitates to single out any particular portion for special comment However, the sections on pessaries, endometrial biopsy and the Rubin test are examples of the fine detail that makes this study so valuable to the practitioner.

The book will prove most useful to the physician who requires a one volume reference on the problems of gynecology

NOTICES

AMERICAN BOARD OF OPHTHALMOLOGY

Because of the war emergency, the American Board of Ophthalmology announces the following additional examinations New York City, December 13 to 16, and Los Angeles, January 15 and 16

At the last meeting, it was decided to cancel the 1943 written examination, to include in the oral examination all the subjects previously covered by the written examination and to dispense temporarily with the requirement of case reports The oral examination will probably require two or three days and will cover the following subjects external diseases (slit lamp), ophthalmoscopy, histology, pathology and bacteriology, ocular motility, refraction and retinoscopy, practical surgery, anatomy and embryology, perimetry, therapeutics and operations optics and visual physiology, and relation of the eye to general diseases

Formal application on the proper blanks for the December and January examinations must be filed with the secretary not later than November 1. Blanks may be obtained from the American Board of Ophthalmology, 6830 Waterman Avenue, St. Louis, Missouri.

YALE UNIVERSITY SCHOOL OF MEDICINE

A postgraduate course on industrial health and medicine in wartime will be given at Yale University School of Medicine on Wednesday afternoons from October 7 to December 23. Under the auspices of the Departments of Pharmacology, Preventive Medicine and Public Health, lectures and seminars will be presented by Drs. W. F. Von Oettingen, Leroy U. Gardner, R. A. Kehoe, Alice Hamilton, Louis Schwartz, Robert S. Goodhart, George R. Cowgill, C.-E. A. Winslow, M. I. Hall, Lydia Giberson, Louis Sachs, A. B. Landry and A. S. Gray; Lieutenant Colonels A. J. Lanza and D. B. Dill; and A. L. Coleman, Everett Martin, B. F. Postman, J. J. Bloomfield and E. P. Chester.

A registration fee of \$10.00 will be charged, and those who attend the course regularly will be given a statement to that effect. Physicians who are interested may obtain detailed information from Dr. W. T. Salter, Yale University School of Medicine, New Haven, Connecticut.

LEWIS CASS LEDYARD, JR., FELLOWSHIP

The Lewis Cass Ledyard, Jr., Fellowship was established in 1939 by a gift from Mrs. Ruth E. Ledyard, wife of the late Lewis Cass Ledyard, Jr., a governor of the New York Hospital. The income, amounting to approximately \$4000 annually, will be awarded to an investigator in the fields of medicine and surgery, or in any closely related field. This amount will be applied as follows: \$3000 as a stipend and, approximately, \$1000 for supplies or expenses of the research. In making the award, preference will be given to younger applicants who are graduates in medicine, and who have demonstrated fitness to carry on original research of high order. The recipient of this fellowship will be required to submit reports of his work under the fellowship, either at stated intervals or at the end of the academic year; and when the result of his work is published, he will be expected to give proper credit to the Lewis Cass Ledyard, Jr., Fellowship. The research work under this fellowship is to be carried on at the New York Hospital and Cornell University Medical College. The fellowship will be available on July 1 at the beginning of the academic year. Applications for the year 1943-1944 should be in the hands of the Committee by December 15. It is expected that the award will be made by March 15, 1943.

Application for this fellowship should be addressed to: Committee of the Lewis Cass Ledyard, Jr., Fellowship, The Society of the New York Hospital, 525 East Sixty-eighth Street, New York City.

NUMBER 10

SIX YEARS' EXPERIENCE OF THE THYROID SERVICE AT THE MASSACHUSETTS MEMORIAL HOSPITALS*

HOLLIS L. ALBRIGHT, M.D.,† AND HOWARD M. CLUTE, M.D.‡

BOSTON

THE Thyroid Service, which was established at the Massachusetts Memorial Hospitals in January, 1936, includes representatives of the associated specialties of otolaryngology and ophthalmology, as well as internists, cardiologists and surgeons. Up to January 1, 1942, the four surgeons on the Thyroid Service, the rotating residents and house staffs have performed three hundred and thirty-four thyroid operations on 288 patients, with 6 deaths, only 1 death having occurred in the last three years (Table 1). The operative mortality was 1.8 per cent, and the patient mortality 2.1 per cent. A review of the operative results has been of value, especially to the surgeons who have served on the hospital and outpatient thyroid services throughout this six-year period, in a realization of what has or has not been accomplished and of plans for future betterment.

Of the entire series, the ratio of females to males was 5.3:1. The youngest patient (exophthalmic goiter) was fifteen years old, and the oldest (carcinoma) seventy-one. Figure 1 shows the age distribution by decades for the toxic and nontoxic groups. As one would expect, exophthalmic goiter is a disease of youth, and nodular goiter one of older patients.

HYPERTHYROIDISM

Exophthalmic Goiter

One hundred and seventy-six operations were performed on 139 patients, with 3 fatalities, the operative mortality being 1.7 per cent. There were 105 females and 32 males, a ratio of 3.3:1. Eighteen of the 30 thyrocardiac cases occurred in the exophthalmic group (Table 1). A patient is described as thyrocardiac when he presents evidence of underlying cardiac damage associated

with hyperthyroidism. Rheumatic, hypertensive and syphilitic heart diseases are most commonly found to be the cause of this damage. Impairment of the cardiac reserve is usually manifested by the presence of preoperative auricular fibrillation or cardiac decompensation, or both. These patients are much more serious operative risks, and all 18 were subjected to a two-stage thyroidectomy, with an interval of six weeks between operations. Two of the three deaths in the exophthalmic group occurred in known thyrocardiac patients, both after the first-stage hemithyroidectomy.

Experience has convinced us beyond doubt that subtotal thyroidectomy in the patient who is a poor risk may be too strenuous a procedure for him to withstand. This is especially true on a teaching service, where the operation may occasionally be prolonged. Therefore, objective evaluation of the patient on the basis of age, weight loss, duration of disease and response to treatment[§] was adhered to in the selection of the operative procedure for each patient. Thus, in the exophthalmic group, 37 per cent of the patients were subjected to a two-stage thyroidectomy. All 3 fatalities in the exophthalmic group occurred during the first three years of the Thyroid Service, and after a first-stage hemithyroidectomy, an indication that all the patients were evaluated preoperatively as serious risks.

Twelve patients developed sufficiently severe postoperative reactions to be classified as suffering from thyroid storm, which, on the Thyroid Service, means the presence of a progressively rising fever and a rapid pulse rate, with or without irregularity, in addition to restlessness, delirium, pulmonary congestion and, in cases that cannot be controlled, a fatal ending. Again, on the basis of objective findings, all 12 patients had given enough preoperative warning, so that only a hemi-

§Clute, H. M. Operative mortality in hyperthyroidism. *J. A. M. A.* 95:389-392, 1930.

in an attempt to arrest the uncontrolled hyperthyroidism. Viewed in retrospect, either preliminary bilateral superior-pole ligation or, even better, a much longer preoperative period might have favorably altered the outcome. The patient had received iodine for one month before admission, and this was perhaps a factor in the poor response to the preoperative management of her hyperthyroidism.

CASE 2. Mrs. S. T., a 69-year-old widow, was admitted to the Evans Memorial on October 13, 1937, complaining of extreme nervousness and rapid onset of the cardinal symptoms of hyperthyroidism during the previous 3 weeks. She had lost 15 pounds during this time, a total of 43 pounds in a year. For 3 weeks, there had been marked palpitation, dyspnea and weakness. There was no ankle edema or chest pain.

Examination revealed an undernourished woman who was nervous and worried, and showed mild activation. The skin was warm and moist. There was no exophthalmos. There was a fine tremor of the extended tongue and fingers. The thyroid gland was symmetrically enlarged to one and a half times the normal size. In addition, a coincidental, discrete 2.5-cm. adenoma was palpated in the right lobe. The heart was slightly enlarged, and the rhythm was regular. However, on the day following admission, paroxysmal auricular fibrillation was noted, and this continued throughout the preoperative course. The blood pressure was 140/78.

The basal metabolic rate was +35 per cent. A photometer reading showed a moderate deficiency in vitamin A. The patient was put on large doses of vitamin A for 15 days, without any real effect on the metabolism, but with marked improvement of the photometer reading. She was then given Lugol's solution, 10 minims three times a day, beginning on the 19th day. On the 36th day, the basal metabolic rate had fallen to -2 per cent (after 17 days' treatment with Lugol's solution). The patient was transferred to the Thyroid Service on the 38th day after admission, when slow auricular fibrillation and moderate cyanosis were evident. She was seen by the cardiologist, Dr. Ashton Graybiel, who considered the cardiac reserve adequate and believed that the patient should be fully digitalized preoperatively. This was done during the next 16 hours.

A first-stage hemithyroidectomy was carried out on November 23, 1937, under cyclopropane and oxygen anesthesia. The patient's condition was satisfactory during the initial stages, and she continued to fibrillate at a slow rate, 50 to 80 beats per minute. The blood pressure, which was 136/94 the day before operation, rose to 184/84 at the beginning of anesthesia and to 214/140 after 10 minutes; the pulse rose to 116. After 14 minutes of operating time, the patient suddenly stopped breathing and became pulseless. In spite of artificial respiration, she could not be revived and died before completion of the operation.

Post-mortem examination revealed no gross, obvious cause of death. The thyroid gland was diffusely hyperplastic. The lungs were essentially normal. The heart showed slight dilatation, and the myocardium was notably soft and flabby. The coronary arteries were sclerosed, with marked fibrous thickening of the intima, in places amounting to almost complete occlusion. Acute cardiac decompensation and acute dilatation of the heart were regarded as the causes of death.

The patient was obviously a very serious risk. She was sixty-nine years old and had lost a large amount of weight (43 pounds) over a period of one year. Latent hyperthyroidism had probably been present for a much longer period than the three weeks of obvious hyperthyroidism. Limited cardiac reserve and actual cardiac damage were present, as shown by auricular fibrillation, dyspnea and palpitation. In retrospect, three questions arise. Would some other anesthetic have been less severe on the patient, would a more conservative operation in the form of pole ligation have been preferable, or should we have taken much longer in our preoperative preparation? In the great majority of serious-risk patients, it is our opinion that the operation can be brought to a speedier conclusion, with less trauma to the patient, under general anesthesia in the form of cyclopropane and oxygen administered by an experienced physician anesthetist. Perhaps, initial ligation of the superior thyroid vessels, first on one side and then on the other, followed by a two-stage hemithyroidectomy, would have helped this patient. In the light of our past experience, single-pole ligation has often failed to arrest the progress of the disease, because of the marked collateral vascularity of the thyroid gland. Consequently, we have placed greater reliance on adequate, rigidly careful preparation of the serious risk patient for a quick hemithyroidectomy. Actually, this has given us greater assurance in arresting and controlling the hyperthyroidism. The questions of whether this patient could have survived four planned, graded, operative procedure or should have had longer preoperative care can not be answered.

CASE 3. W. M., a 53-year-old dyer, was admitted to the hospital on November 3, 1938, complaining of increasing irritability, nervousness and a loss of 34 pounds in 1 year. Symptoms including crying spells were severe for 3 months and iodine (5 drops three times a day) had been taken for 12 months before admission. Dyspnea, orthopnea and ankle swelling had been noted for 2 weeks. One brother had died of "goiter" at the age of 34 years.

Examination revealed an 118-pound man who was excited, mentally confused, indifferently co-operative and unreliable in history. There was exophthalmos of the right eye only. The thyroid gland was firm and symmetrically enlarged to three times the normal size. There was no heart disease.

The basal metabolic rate was +53 per cent on admission, and 14 days later +16 per cent. However, the patient lost 5 additional pounds during that period.

Sixteen days after admission, a right hemithyroidectomy was performed, without incident. The course was uneventful for 24 hours, when a temperature of 103°F. and auricular fibrillation at the rate of 130 beats per minute developed. The patient responded well to intensive supportive

therapy until the afternoon of the 2nd day when his temperature rose to 106°F. Ice packs and sodium amylal by rectum produced temporary improvement, without evidence of cardiac failure. However, the patient died suddenly that night, 61 hours after operation, of uncontrolled thyroid crisis. Autopsy revealed bronchopneumonia and pulmonary edema, but no other cause of death.

Adenomatous Goiter with Hyperthyroidism

Forty-seven operations were performed on 40 patients, with 2 deaths, giving an operative mortality of 4.3 per cent. The youngest patient was twenty-five years and the oldest seventy years of age. Twenty-nine patients were over and 11 under forty years. There were 36 females and 4 males, a ratio of 9:1. Many of these patients had had asymptomatic goiter for years, the longest duration being forty years. Relief was sought only when complications, especially hyperthyroidism, appeared. Thyroidectomy was performed in two stages on 7 patients, or 18 per cent of the cases.

Pathological examination disclosed areas of secondary hyperplasia in the multiple colloid adenomatous goiter in 26 cases. In the remaining 14 cases, multiple colloid adenomatous goiter was reported, with associated fetal or embryonal adenomas in 3 cases, secondary hemorrhages in 3 and associated simple adenomas in 4. These 14 patients were considered to have so much clinical evidence of hyperthyroidism that they were so classified, even though the pathological examination did not disclose substantiating hyperplasia.

There were 9 thyrocardiac patients, and 1 death occurred in this group. Another patient developed postoperative thyroid crisis, terminating in death after forty hours. Two patients recovered from impending crisis. Three patients had transient auricular fibrillation postoperatively.

Four hours after operation, the one postoperative hemorrhage of the entire series occurred in this group. Secondary operation for control of the hemorrhage was followed by uneventful recovery. One patient had transient immobility of the left vocal cord that cleared in two months. One patient sustained permanent injury to the left vocal cord, which was present thirty-seven months later. There was no case of bilateral nerve injury in the entire series. No patients were known to have developed recurrent hyperthyroidism, hypothyroidism, myxedema or hypoparathyroidism.

The 2 fatal cases are reviewed below.

CASE 4. G. G., a 67-year-old man, was admitted to the hospital on November 25, 1936, with a swelling of the neck that had been present since childhood and had shown gradual growth in the preceding 12 years. For 6 months increased warmth, marked tremor of the hands and extreme weakness had developed with no loss of weight. The neck had become smaller, that is, a size 20 collar

became too large, suggesting descent of the goiter into the upper mediastinum.

Examination revealed a 168 pound, well-preserved man showing definite activation, with tremor of the extended tongue and fingers. The thyroid gland on the left was replaced by a nodular mass five times the size of the normal lobe; the right lobe was smaller but enlarged. The trachea was deviated to the right with moderate compression. The heart showed no gross enlargement. The pulse rate was 100.

The basal metabolic rate was +31 per cent, and 11 days later, it was +19 per cent. Two days before operation, the pulse rate rose to 148, and auricular fibrillation developed. The patient was digitalized, 15 gr being given over the 2-day period before operation.

A first-stage hemithyroidectomy was done 3 weeks after admission. The next day, the patient's condition was considered very satisfactory, with the pulse regular at 70 beats per minute, and the temperature 100.6°F. That afternoon, 90 minutes after an intravenous infusion of 750 cc of 10 per cent glucose and Lugol's solution (10 minims in physiologic saline solution), the patient developed a chill, became cyanotic and fibrillated. Respirations rose to 35 per minute. Despite oxygen and uninterrupted digitalis therapy, the temperature rose steadily to 104°F by axilla, and the patient became semicomatose, pulmonary congestion developed, without edema. He died 40 hours after operation.

The cause of death was regarded as postoperative thyroid crisis leading to failure of first the pulmonary and then the general circulation. No definite opinion could be formed concerning the possible precipitating effect of the intravenous infusion. Autopsy revealed no significant local changes and substantiated the clinical impression of the cause of death.

A review of the preoperative management of this patient brings to the fore the sudden development of auricular fibrillation for the first time two days before operation. This certainly gave a further warning of the serious risk involved in this patient. A longer period of digitalization and cardiac therapy might have averted the fatal outcome. From this and other experiences, we believe that when digitalization is carried out, a delay of several days in operation should follow.

CASE 5. Mrs. A. S., a 61-year-old woman, was admitted to the hospital on November 26, 1941, with goiter for 20 years and symptoms of hyperthyroidism for 8 months. Lugol's solution, 15 minims daily for 6 months, had been attended by temporary improvement followed by progressively severe hyperthyroidism. The patient had lost 15 pounds in the previous year.

Examination revealed a thin, activated elderly woman in the iodine fast state of hyperthyroidism. The thyroid gland was nodular and enlarged to four times the normal size on the right and slightly less on the left.

The basal metabolic rate was +48 per cent, and 8 days later was +46 per cent. The pulse rate ranged from 76 to 128, and on the morning of operation was 76.

Fifteen days after admission, a right hemithyroidectomy was done without difficulty. Six hours later, the temperature rose to 105°F, and the classic picture of thyroid crisis developed. On the 2nd postoperative day, auricular premature systoles were disclosed by electrocardiogram. The pulse rose to 200 per minute, and the temperature

ranged from 103 to 105°F.; coma and death occurred on the 3rd postoperative day.

The cause of death was uncontrolled hyperthyroidism; post-mortem examination disclosed no other cause.

Recurrent Hyperthyroidism

Twenty operations were performed on 18 patients who had had previous operations for hyperthyroidism. There were no deaths. Five patients were considered to have persistent hyperthyroidism following operation within the previous two years. The remaining 13 patients had been free from symptoms for from two to twelve years; these were regarded as patients with recurrent rather than persistent hyperthyroidism. All patients appearing for secondary operations for the control of hyperthyroidism have been grouped under the single term "recurrent," however, for the management of both the persistent and truly recurrent cases is identical.

Sixteen patients originally had diffuse goiter of the exophthalmic type, confirmed pathologically as primary hyperplasia of the recurrent remnant. Only 2 showed recurrent nodular goiter with secondary hyperplasia of the remnants.

Fifteen patients had a one-stage reoperation. Two had divided reoperations at six-week intervals. One patient required two reoperations, twelve and thirty months, respectively, after the original thyroidectomy for exophthalmic goiter. There were 3 thyrocardiac patients, in all of whom only single-stage reoperation was necessary.

Preoperative examination of the vocal cords, although desirable in all patients undergoing thyroidectomy, is especially so in those on whom reoperation is contemplated. One patient had paralysis of the left vocal cord following thyroidectomy thirty-seven months previously. Such information aids greatly in averting possible further damage and bilateral vocal-cord paralysis.

None of these patients developed postoperative hemorrhage, thyroid crisis or recurrent-laryngeal-nerve injury. One patient, who developed clinical tetany from hypoparathyroidism on the fourth postoperative day, had had two operations for exophthalmic goiter, eight and seven years previously. Two months after the onset of mild tetany, she was adequately controlled on a regime of calcium and dihydrotachysterol (AT 10), but continued therapy was necessary. One patient developed hypothyroidism and myxedema a year after operation.

NODULAR GOITER WITHOUT HYPERTHYROIDISM

All 74 patients in this group were subjected to single-stage thyroidectomy, and there were no fatalities. Many of the goiters were described as

subclavicular and substernal in position, and several as intrathoracic. However, none were so truly intrathoracic as to require splitting of the sternum or to cause undue technical difficulty of removal through the usual thyroidectomy approach.

The distribution of the pathologic types encountered is presented in Table 3. Much emphasis

TABLE 3. *Summary of Cases of Nodular Goiter without Hyperthyroidism.*

YEAR	TOTAL No. OF CASES	DIAGNOSES		
		MULTIPLE COLLOID ADENOMATOUS GOITER	SIMPLE ADENOMA	FETAL ADENOMA
1936	3	1	2	0
1937	12	6	6	0
1938	16	5	9	2
1939	16	9	6	1
1940	9	5	3	1
1941	18	8	10	0
Totals	74	34	36	4

has been laid on the parenchymatous, embryonal or fetal adenoma as representing a true tumor type, in contrast to the colloid or simple adenoma. The parenchymatous adenoma was found in only 4 patients, and the colloid adenoma in 36—nine times more frequently.

The postoperative complications were limited to one permanent and one transient unilateral recurrent-laryngeal-nerve injury that cleared in ten weeks. One patient developed coincidental catarrhal jaundice on the third postoperative day. No deaths occurred.

CARCINOMA OF THYROID GLAND

Seven patients with thyroid carcinomas were operated on during this six-year period. In 5 cases, radical thyroidectomy was carried out, but in none were the cervical lymph nodes or internal jugular vein removed. The remaining 2 patients were subjected to biopsy only, and 1 of these died of myocardial failure on the eighth postoperative day. The surviving 6 patients received postoperative x-ray treatment.

A fifty-one-year-old patient who showed clinical hyperthyroidism associated with unsuspected carcinoma had had symptoms of hyperthyroidism for eight months, with a loss of 12 pounds and an initial metabolic rate of +50 per cent. A subtotal thyroidectomy was done for exophthalmic goiter. However, pathological examination revealed papillary adenocarcinoma in one portion of the diffuse primary hyperplasia seen throughout. The metabolism was -6 per cent seven days later. Examination twenty-six months later revealed the patient to be symptom free, with no signs of recurrence.

Except for the 1 fatality, which is reviewed below, there were no complications. The 6 sur-

viving patients have remained symptom free for four to twenty six months after operation

CASE 6 Mrs A A, a 71 year old housewife, was admitted to the hospital on February 4, 1938, having noted swelling of the left side of the neck for 6 weeks. She had lost 35 pounds and had noted hoarseness for 3 weeks. The swelling grew constantly larger and more painful during this short period.

Examination revealed a well preserved woman with normal findings except for hoarseness and the swelling of the neck. The left lobe of the thyroid gland was enlarged to four times the normal size, the mass was hard and fixed, and involved the isthmus. The right lobe was not palpably enlarged. There were several hard, cervical lymph nodes, 1 cm in diameter, on the right. The trachea was displaced to the right. General arteriosclerosis was evident.

Biopsy of the thyroid gland was performed 10 days after admission. The pathologist reported a rapidly growing exceedingly anaplastic, embryonal tumor, probably of thyroid origin. On the 2nd postoperative day, the patient developed progressive signs of myocardial failure, and succumbed on the 8th day after operation. No autopsy was performed.

The problem of managing the patient with a solitary thyrogenic metastasis of the skull has arisen once in this series. Active intervention, with removal of the long standing calcified malignant adenoma of the right thyroid lobe, followed by craniotomy and removal of the skull metastasis, was carried out. No further recurrence had appeared twelve months after operation.

RARER CONDITIONS

Three patients were seen with parathyroid adenoma, profoundly altered calcium metabolism and bone changes. One was moribund on admission. Excision was carried out on the remaining 2 cases. One patient survived and made a striking, sustained recovery. These records are being prepared for publication.

The congenital anomalies were few in this series. Lateral aberrant thyroid tissue was removed from the neck in 2 cases. Persisting remnants of the thyroglossal duct were also removed from 2 patients. No patients with lingual thyroid tissue were seen. No complications and no deaths occurred in this group.

SUMMARY

A six year review of the Thyroid Service at the Massachusetts Memorial Hospitals is presented. Since this is a general ward service, many of the seriously ill patients first appeared in advanced untreated stages of thyroid disease. They showed evidences of dietary deficiencies and constitutional disease. In the treatment of such patients, our experience has justified, we believe, the relatively high rate of divided operations (31 per cent) in the 197 patients with hyperthyroidism. In spite

of this conservative approach, a thyroid crisis developed in 16 of these 197 patients, 4 of whom died. It is apparent that in a ward thyroid service, therefore, one must take a longer time and give more detailed care in the preoperative preparation of patients with hyperthyroidism if the same low mortality figure as that among private patients is to be obtained.

The morbidity and mortality rates have been constantly kept before us in our efforts to improve these results. Although the mortality rate of 17 per cent among patients with exophthalmic goiter conforms with results generally obtained, it is interesting that no patient died of this disease during the last three years.

The patients having adenomatous goiter with hyperthyroidism showed a mortality of 4.3 per cent. There were 2 deaths in the 40 cases, both due to thyroid crisis. Associated cardiovascular impairment was present in 23 per cent of these cases, whereas only 13 per cent of the exophthalmic group showed this complication. These patients were on the average much older than the exophthalmic patients, and the goiter was of long standing.

There was no mortality in the eighteen secondary operations for recurrent toxicity.

The four permanent, unilateral recurrent laryngeal nerve injuries represent a rate of 1.2 per cent in three hundred and thirty four thyroid operations. An additional 3 patients, 0.9 per cent, sustained temporary nerve injury such as may result from undue traction, crushing or hemorrhage into the nerve area, with demonstrated recovery of function in two to twenty eight weeks. Postoperative hypothyroidism and myxedema were noted in 12 of 288 patients, a rate of 4.2 per cent. This complication is far preferable to persisting toxicity and, in certain thyrocardiac patients, is even desirable. If necessary, it is readily treated.

The long continued use of iodine in the unoperated patient with hyperthyroidism was discouragingly frequent. These patients were more difficult to prepare for surgery, the operative risk was greater, the postoperative reaction was less amenable to control, and a fatal outcome was more frequent. Three patients, or 60 per cent of those who died in the hyperthyroid group, had been given daily iodine for from one to six months before surgery was advised and carried out.

Experience has led us strongly to advise against the use of iodine in these patients until active plans for surgical treatment have been made by the physician and agreed to by the patient. Attempts to control hyperthyroidism with nonsurgical measures not only delay unjustifiably, we believe, ef

fective control of the disease, but increase the likelihood of complications before and after thyroidectomy and thereby lessen the usual safety of the procedure. The iodine-fast patient with hyperthyroidism should disappear as soon as physicians are

ready to accept the facts that surgery is a safe and rapid method for curing hyperthyroidism and that, in outspoken thyroid toxicity, iodine does not produce a cure.

412 Beacon Street

THE PHYSICIAN PREPARES TO ENTER THE ARMY

ROBERT M. ZOLLINGER, M.D.,* AND MARK A. FREEDMAN, M.D.†

BOSTON

THE proposed increase in the size of the Army of the United States indicates that many physicians will find themselves in the armed services in the near future. The average physician is so busy with everyday practice that he has little time to think about the multiple preparations necessary before he enters the service. Many questions arise regarding how to proceed to close the office, provide for dependents and prepare for entrance into the Army. Having experienced these problems and answered many inquiries, we offer the following suggestions. Although many of these suggestions are obvious and others may be outdated or changed radically before this article is published, some of them may be helpful.

CLOSING OFFICE

One should take an inventory of all instruments, equipment and furniture and evaluate these articles in case it becomes necessary to sell them or to collect insurance for fire or theft.

One should arrange for storage of equipment and see that it is fully covered by insurance, unless it is to be used by another physician.

All narcotics should be locked up or returned for credit; it is not necessary to renew the narcotic license.

All case histories, especially cases in which litigation may be involved, should be completed. A physician who is entering the service should instruct his representative or attorney in the use of his files and their contents.

Accounts payable and receivable should be audited and explained in detail to the representative or attorney. A note should be appended to statements rendered for professional services informing patients that one is called to active duty, since this appeal often brings results.

Office subscriptions to popular magazines should be canceled. It is usually wise to continue profes-

sional journals, with a change of address, until one is certain that they are available in hospital libraries of future stations.

Arrangements to cancel or adjust rent or sublet office space should be made. If the renewal of the lease for office space is due in the near future, and there is a possibility of one's being called to active duty, this renewal should contain an army clause to become effective on the date of call to service.

Service for gas, electric light, telephone, laundry and so forth, should be canceled.

Employees should be provided with a letter of recommendation.

Since service in the Army does not release one from the danger of malpractice suits, it is wise to maintain professional protective insurance. However, the validity of such insurance, while one is on duty, especially on foreign soil, should be checked—some companies are issuing a special low-cost policy covering malpractice insurance in military service. The insurance company should be notified of entrance into the service and change of address.

All medical societies of which one is a member should be notified of the date of call to service. Many societies will keep the names of those entering the armed forces on their inactive list until they return, without financial obligation.

It is advisable to take along any instrument, such as an ophthalmoscope or stethoscope, that one has become accustomed to using with ease and without which one may be handicapped.

A request for leave of absence should be written to the secretary of the staff of the hospitals and medical school where appointments are held, or with which one has been affiliated.

It is a matter of personal opinion of how best to notify patients of entrance into the services. This may be done by personal calls, printed announcements or form letters. If one's practice has been assumed by another physician, this fact may also be announced by the above methods.

*Major, United States Army Medical Corps.

†Captain, United States Army Medical Corps.

PROVIDING FOR DEPENDENTS

The chief concern of most physicians will be providing for the family. Budgets must be readjusted to the new fixed income (Table 1). It

are not given a rental allowance. While one is on duty in the United States, allotments of pay can be made only for payment of governmental or commercial life-insurance premiums. On duty out-

TABLE 1. *Approximate Pay of Medical Officers.*

FRACITION	FIRST LIEUTENANT		CAPTAIN		MAJOR		LIEUTENANT COLONEL	
	MARRIED	SINGLE	MARRIED	SINGLE	MARRIED	SINGLE	MARRIED	SINGLE
Base pay	166.67	166.67	200.00	200.00	250.00	250.00	291.67	291.67
Rental allowance	60.00	40.00	80.00	60.00	100.00	60.00	120.00	80.00
Ration allowance	36.00	18.00	36.00	18.00	54.00	18.00	54.00	18.00
Totals	262.67	224.67	316.00	278.00	404.00	328.00	465.67	389.67

is wise to plan this readjustment early, so that all changes will be gradual and all eventualities may be foreseen.

It is unwise to plan on moving the family until it can be determined when one will be called and where the first permanent station will be located. The first station may be near one's present home. Taking the family is unsatisfactory, since adequate living quarters near army camps are difficult to find, rents are invariably high and there will be frequent and unpredictable changes of station.

It is essential to consult a competent lawyer in planning and settling one's business affairs.

A last will and testament should be made, regardless of dependents.

A power of attorney should be granted the wife or another trustworthy and competent person, so that one's business may be managed properly. A limited power of attorney may be given a secretary, who is familiar with the accounts payable and receivable that will continue for a time after the office is closed.

All documents, such as deeds, wills, insurance policies, copies of power of attorney and birth certificates, should be stored in a safety deposit box accessible to the wife and attorney.*

ARMY PAY AND ALLOTMENT

For the first time, the majority of physicians will receive a relatively fixed salary, varying only with rank, length of service and special compensation for service overseas. This salary, which is paid once a month in cash or by check, may be deposited by the local finance officer in the bank of one's choice. Each officer receives a 5 per cent increase in base salary when he completes three years of active duty, six years of inactive duty or any equivalent combination of service. This is known as a "fogey." A 10 per cent increase in base pay is provided when an officer serves overseas. Single officers, living in adequate quarters provided by the Government,

side the continental limits of the United States or in Alaska, one can allot any or all of the base pay, longevity and ration allowance to any bank or insurance company. These amounts can be calculated from Table 1.

Single officers with dependents may receive married officers' salaries if the dependency is adequately proved by certification and affidavits.

INSURANCE

Since many physicians have major investments in insurance, this subject deserves special consideration.

The validity of all insurance policies while one is in service should be reviewed. Most policies issued during the latter half of 1941 contain a war clause. The clauses that govern the continuation of policies in the event that one is unable to pay the premiums should be clarified. Such problems can be discussed with any competent insurance broker or a qualified representative of the insurance company. There are no set rules for insurance, since each policy is an individual contract, and policies vary with the company and the type of coverage. Although no set directives can be given, the following suggestions may prove of benefit.

A résumé of all insurance policies, listing the name of the insurance company, type of insurance, amount of policy, amount of premium and date on which the premium is due, should be prepared. Copies should be furnished to the persons designated to manage the affairs of the physician who enters the service.

A permanent mailing address (not an army address) should be established in one's name in care of the wife or attorney, so that premium notices will be received and paid promptly.

In general, policies lapse in thirty-one days if the premiums are not paid. A statement of health must be submitted in the following thirty-day period, or policies are finally dropped. Absence without proper safeguards and the impossibility of quick communication invite this danger. If ninety

*LaGarde, R. D. Concerning dependents. *Coast Artillery* 1 85:14 (Mar-Apr), 1942.

days have elapsed, the policy may then be considered void, and the company may refuse to reinstate the policy on payment of back premiums or may reinstate the policy with a war clause inserted.

It is possible to pay up policies for more than a year in advance by a single cash payment. Interest usually accrues at bank rates, and any excess is refunded if the policy is terminated.

Information should be obtained regarding what happens to each policy if one is unable to pay the premiums from current income.

The better plan is that incorporated in an "automatic premium loan clause." This permits the use of the cash value of the policy for payment of future premiums. If not already included, this clause should be written into the contract. If it is planned to use this method of payment, written authorization must be given to the company. This is not applicable to term insurance, which has no loan value.

If the company will not grant the automatic premium loan option, the policy is governed by the so-called "nonforfeiture option." This option provides the choice of accepting a reduced amount of paid-up or extended insurance at its full value until the cash value of the policy is used up. This selection seems desirable in providing full protection during service in the Army.

Double indemnity is usually not paid in war except for fatal accidents common to civilian life. The disability clause does not hold during military service. Some companies will refund this portion of the premium on a pro-rata basis. Likewise, some companies will reinstate the disability clause after return to civil life if a medical examination is passed.

Is the policy invalidated by airplane travel? If not, is there any limitation concerning the type of carrier and number of flights. In many policies, double indemnity is not paid except in fatal accidents occurring on regular fare-paying passenger lines. Double indemnity would not be paid for accidents occurring in the Army Air Corps.

Term insurance especially must be analyzed. If it is necessary to convert it while one is in service, one should make certain that the war clause is not inserted. One must provide the additional money necessary for conversion back to the date of purchase, to avoid insertion of the war clause. If term insurance is converted gradually, the dates of conversion and amount of increase of premium must be carefully explained to those responsible for paying the insurance premium. An immediate conversion to ordinary life insurance is advisable if financially possible.

To avoid nonpayment of premium, it is possible, if on duty outside continental United States or in Alaska, to have the Government pay premiums directly to the insurance company and make the necessary deduction from base pay. This is called "payment by allotment." It will be necessary to adjust the premium to a monthly payment plan, for annual and quarterly payments are not possible by allotment.

Government insurance is available up to \$10,000. This cheap and highly desirable insurance may be obtained by consultation with the adjutant of the organization. It is not available until after induction into the service. Although it is initially term insurance, it may be converted after a year and before five years have elapsed. The monthly premiums vary from \$7.10 at thirty years of age to \$8.50 at forty.

The advisability of continuing health and accident insurance policies should be considered, since the benefits from these policies are limited while the physician is in the armed services. Most policies are good only for conditions common to civilian life in the United States. Noncancelable policies merit special consideration, for they may be impossible to obtain when one returns to civilian life.

All other types of insurance should be renewed, and one should be certain that coverage is complete for fire, theft, liability and so forth on car, household goods and real estate. Adequate preparation for payment of such premiums, many of which fall due every three years, should be made.

All policies should be stored in a safety deposit box.

It is wise to provide the wife or attorney with a copy of marriage certificate and birth certificates of oneself, wife and dependents so that relationship may easily be proved if it becomes necessary to collect pensions or insurance. These documents should be placed in a safety deposit box.

TAXES AND MORTGAGES

Service in the Army does not excuse one from payment of taxes. Although the Soldiers and Sailors Civil Relief Act of 1940 permits deferment of payment of federal taxes by members of the armed forces, this deferment is not automatic. Inability to pay taxes from current income must be proved by the submission of a sworn statement of financial condition at the time the tax return is filed. The attorney should be provided with a list of taxes payable and the dates on which they are due, and with all information necessary to file income-tax returns on income from practice and investments. Arrangements should be made for

payment or readjustment of any mortgages that may be held. Army salaries are subject to the state and federal income taxes.

Although the Relief Act of 1940 provides protection for men in the service on certain other classes of debt in and prior to the passage of the act, one should consult a competent attorney in any specific case in which relief is desired.

UNIFORM

It is customary to report for active duty in uniform. It is, of course, a great temptation to buy an extensive wardrobe. It cannot be overemphasized that one should purchase only a minimum of clothing. Great savings and better selection can be effected if one purchases most articles from the post exchange and quartermaster after reporting for duty.

The prescribed uniform varies with the type of assignment and with the climate. A safe minimum purchase providing a standard dress uniform regardless of the location of station or time of year is as follows:

- 1 overseas cap.
- 1 woolen blouse with cloth belt (Sam Browne belts are no longer required).
- 1 pair of woolen trousers (either 'pink' or to match blouse).
- 1 cotton shirt
- 1 woolen shirt (field).
- 1 web belt (plain buckle).
- 2 pairs of solid color tan or brown socks
- White or tan handkerchiefs
- 1 necktie of new M-3 shade (black ties are no longer worn).
- 1 overcoat (if possible, one should not buy an overcoat until arrival at post; if weather is inclement, a gabardine raincoat may be worn)
- 1 complete set of insignia (one should refer to *Officer's Guide* for correct placement on uniform).

All solid tan and brown shoes are acceptable.

(It is not considered necessary to wear any special military shoe unless one is ordered to do so. One should remember that there is much walking and marching during the initial period of training on active duty, and should provide oneself with a pair of comfortable, waterproof, well broken in high shoes.)

Every article of clothing should be marked with one's name. Rank and name of organization should be omitted. Linen or rayon tape, embroidered or stenciled with indelible ink, is most frequently used. A timesaving device is a rubber name stamp with an indelible ink pad for stenciling flat pieces, such as handkerchiefs, sheets and towels.

All personal effects should be stored, and all woolen clothing should be cleaned and made mothproof before storage.

Useful reference books that may be purchased are *Officer's Guide* (seventh edition—February, 1942), *Military Medical Manual* and *Handbook of the Medical Soldier*.

The following luxuries will add much to one's comfort and enjoyment during camp life but are not essential: radio, camera, electric razor, spot-type bed lamp, small bedside floor rug and so forth.

The change from civilian to army life is radical, and yet the readjustment is rapid, and many a busy physician will appreciate the change. Incidentally, he may be called on to assume the responsibility of doing his own laundry. If so, all woolens should be treated with due respect and washed carefully in lukewarm water. Many a new officer has been horrified by the atrophy of his beautiful hand knit socks following his first effort at the wash tub.

days have elapsed, the policy may then be considered void, and the company may refuse to reinstate the policy on payment of back premiums or may reinstate the policy with a war clause inserted.

It is possible to pay up policies for more than a year in advance by a single cash payment. Interest usually accrues at bank rates, and any excess is refunded if the policy is terminated.

Information should be obtained regarding what happens to each policy if one is unable to pay the premiums from current income.

The better plan is that incorporated in an "automatic premium loan clause." This permits the use of the cash value of the policy for payment of future premiums. If not already included, this clause should be written into the contract. If it is planned to use this method of payment, written authorization must be given to the company. This is not applicable to term insurance, which has no loan value.

If the company will not grant the automatic premium loan option, the policy is governed by the so-called "nonforfeiture option." This option provides the choice of accepting a reduced amount of paid-up or extended insurance at its full value until the cash value of the policy is used up. This selection seems desirable in providing full protection during service in the Army.

Double indemnity is usually not paid in war except for fatal accidents common to civilian life. The disability clause does not hold during military service. Some companies will refund this portion of the premium on a pro-rata basis. The prescribed uniform varies with the type of assignment and with the climate. A safe minimum purchase providing a standard dress uniform regardless of the location of station or time of year is as follows:

- 1 overseas cap.
- 1 woolen blouse with cloth belt (Sam Browne belts are no longer required)
- 1 pair of woolen trousers (either "pink" or to match blouse).
- 1 cotton shirt
- 1 woolen shirt (field)
- 1 web belt (plain buckle)
- 2 pairs of solid color tan or brown socks
- White or tan handkerchiefs
- 1 necktie of new M-3 shade (black ties are no longer worn).
- 1 overcoat (if possible, one should not buy an overcoat until arrival at post, if weather is inclement, a gabardine raincoat may be worn)
- 1 complete set of insignia (one should refer to *Officer's Guide* for correct placement on uniform).

All solid tan and brown shoes are acceptable.

(It is not considered necessary to wear any special military shoe unless one is ordered to do so. One should remember that there is much walking and marching during the initial period of training on active duty, and should provide oneself with a pair of comfortable, waterproof, well broken-in high shoes.)

Every article of clothing should be marked with one's name. Rank and name of organization should be omitted. Linen or rayon tape, embroidered or stenciled with indelible ink, is most frequently used. A timesaving device is a rubber name stamp with an indelible ink pad for stenciling flat pieces, such as handkerchiefs, sheets and towels.

All personal effects should be stored, and all woolen clothing should be cleaned and made moth proof before storage.

Useful reference books that may be purchased are *Officer's Guide* (seventh edition—February, 1942), *Military Medical Manual* and *Handbook of the Medical Soldier*.

The following luxuries will add much to one's comfort and enjoyment during camp life but are not essential: radio, camera, electric razor, spot type bed lamp, small bedside floor rug and so forth.

The change from civilian to army life is radical, and yet the readjustment is rapid, and many a busy physician will appreciate the change. Incidentally, he may be called on to assume the responsibility of doing his own laundry. If so, all woollens should be treated with due respect and washed carefully in lukewarm water. Many a new officer has been horrified by the atrophy of his beautiful hand knit socks following his first effort at the wash tub.

EXPERIMENTAL APPLICATION OF SULFONAMIDE DRUGS TO THE CEREBRAL CORTEX*

FRANC D. INGRAHAM, M.D.,† AND EBEN ALEXANDER, JR., M.D.‡

BOSTON

BECAUSE of war conditions, widespread use of the sulfonamide drugs in wounds of all parts of the body has developed. The obvious effectiveness of these chemicals in helping to minimize infections¹ has resulted in their clinical employment with very little experimental basis, whereas ordinarily there would be ample opportunity for

wise made available to the interested medical public. Several extensive projects are now under way, and it is probably just as well that these be made by several observers, since important discrepancies in results have already been reported. Pilcher and his associates,² who are carrying on an investigation of the chemotherapy of intracranial infections,

FIGURE 1. Cat No. 1.

thorough laboratory trial. This has been particularly true in craniocerebral injuries, in which the opportunity for clinical trial has been all too readily available.

It is apparent that experimental control of this type of chemotherapy,—that is, direct application to the brain and meninges,—is being undertaken in many laboratories, and some surgeons have had an opportunity to see even late effects of such application in patients. To date, extraordinarily little accurate information has been published or other-

were so impressed by the harmful effects of the use of sulfathiazole that they published a preliminary report on the convulsions produced by intracranial implantation of sulfathiazole. Almost concurrently with their report, Penfield,³ following a trip to Great Britain, refers to the fact that some British neurosurgeons have been so favorably impressed by the effect of local application of sulfathiazole that they have taken to placing it routinely within all craniotomy incisions before closure. It seems obvious that the experimental phase of this problem lags considerably behind the clinical. Probably the most complete and most valuable work reported so far, from the Montreal Neurological Institute, was summarized recently by Hurteau.⁴

*From the Department of Surgery of the Children's Hospital and the Harvard Medical School

†Neurosurgeon, Children's Hospital, associate in neurosurgery, Peter Bent Brigham Hospital, associate in surgery, Harvard Medical School.

‡Assistant in surgery, Harvard Medical School.

Undoubtedly, other complete studies will be reported in the near future.

In the hope that some unnecessary duplication of effort may be avoided, these somewhat simpler preliminary experiments are recorded. Sulfanilamide, sulfathiazole and sulfadiazine were applied to the cortex of cats under sterile and unsterile conditions, and since we were most interested in the use of sulfadiazine, this drug was applied to the surface of the brains of three monkeys.

The cat experiments were carried out as follows. With full aseptic surgical technique, a midline incision was made, the temporal muscles incised, and a trephine opening 1.5 cm in diameter made in

repeated, the animal was sacrificed at the end of twenty-nine days, and a mild inflammatory reaction was found.

It is interesting that, except for the control

TABLE 1 Summary of Cat Experiments

Cat No	Drug Used	Postoperative Day Killed	Findings on Traumatized Side	Findings on Nontraumatized Side
Operation performed under sterile conditions				
86	None	14	Normal	Normal
87	Sulfanilamide	36	Normal	Normal
84	Sulfathiazole	7	Normal	Normal
70	Sulfathiazole	29	Mild inflammation	Mild inflammation
25	Sulfadiazine	23	Normal	Normal
Operation performed under nonsterile conditions				
89	None	5	Severe meningoencephalitis	Severe meningoencephalitis
1	Sulfanilamide	29	Dura adherent	Dura adherent
2	Sulfathiazole	14	Normal	Normal
3	Sulfadiazine	26	Normal	Normal

the parietal bone on both sides. The dura was opened on both sides, and on one side, the pia arachnoid was torn and the cortex was traumatized very superficially with a sharp needle. In the control animal, no drug was used. The sulfonamide drugs, in powder form, were applied to the cortex of both sides and to the superficial tissues. Five tenths of a gram of powder was used in each case, a definite layer completely covering the exposed brain being obtained. In a second group of animals, the same operation was then carried out, and drugs were applied under nonsterile conditions, the instruments used were clean but not sterilized, the animals were not shaved, and no cleansing agent was applied to the skin. The results of these experiments are shown most clearly in Table 1 and Figures 1 and 2.

In general, there was surprisingly little reaction to the drugs. One cat in which sulfathiazole was used died seven days after operation, and the cause of death was not clear. Other investigators⁵ have reported that animals in which sulfathiazole was used have had convulsions and have died, presumably because of local irritation and absorption of the drug. In the animal in our experiment, no convulsions were observed, and the survival time seems long for death to have been due to absorption of the drug. When the experiment was

animal that developed a severe meningoencephalitis, the cats subjected to operation under nonsterile conditions did extremely well. There was a slight

TABLE 2 Summary of Monkey Experiments

Monkey No	Bone Flap	Drug Used	Postoperative Day Killed	Findings
1	Not replaced	Sulfadiazine	54	Adhesions of muscle dura and cortex
2	Replaced	Sulfadiazine	45	Inflammatory reaction in dura
3	Replaced	Sulfadiazine	45	Normal

inflammatory response to the drugs, but no actual infection, and when sulfadiazine was used there was no perceptible inflammation.

Since sulfadiazine is probably the most effective of the three drugs in inhibiting the growth of a variety of organisms that would be likely to contaminate war wounds, we were most interested in its application to the cortices of three monkeys (*Macacus rhesus*). A bone

turned down under sterile conditions, the dura opened widely, and 0.5 gm. of sulfadiazine powder

fifty-four days. In the second experiment, there was a mild inflammatory reaction in the dura, and

FIGURE 3. Monkey No. 1.

This monkey was operated on with sterile precautions, the bone flap not being replaced; sulfadiazine was added. The upper photograph shows the gross appearance of the brain, before and after removal of the dura; the temporal muscle was adherent at the site of the flap. The lower photograph shows a section of the cerebral cortex at the site of the adhesion ($\times 125$).

spread over the cortex, dura, bone and superficial tissues. The experiments are summarized in Table 2. In one experiment, the bone flap was not replaced, and dense adhesions between muscle, dura and cortex resulted, as shown in Figure 3, taken when the animal was sacrificed at the end of

a collection of the powder was still grossly visible under the bone flap after forty-five days (Fig. 4). In this and the third experiment the dura stripped away from the arachnoid without any adhesions, and no drug was visible on the surface of the brain.

Unfortunately, these monkeys were extremely difficult to handle, and it was possible to make only a remarkably little inflammatory reaction except in the control cat under nonsterile conditions

FIGURE 4 Monkey No. 2

This monkey was operated on with sterile precautions; sulfadiazine was added and the bone flap replaced. The upper photograph shows the gross appearance of the brain before and after removal of the dura and the inner surface of the bone flap where some of the drug still remained. The lower photograph shows a section of the cerebral cortex ($\times 125$).

postoperative blood and spinal fluid determinations in only one. On this occasion, twenty-four hours postoperatively, the blood sulfadiazine level was 17 mg per 100 cc, and the spinal fluid level 10 mg per 100 cc.

SUMMARY

Sulfamilamide, sulfathiazole, and sulfadiazine were applied directly to the cerebral cortex of 7 cats under sterile and nonsterile conditions. There

Sulfadiazine was applied to the cerebral cortex of 3 monkeys. There was no perceptible inflammatory reaction, except in one, in which the bone flap was left out.

One may conclude that sulfadiazine powder, which is generally agreed to have a bacteriostatic action on the widest variety of organisms, can be safely used in the presence of gross contamination when the brain is not severely damaged. Further

work must be done to determine whether or not this conclusion can be applied to more complex craniocerebral injuries.

MEDICAL PROGRESS

VIRUS PNEUMONIAS. II. PRIMARY ATYPICAL PNEUMONIAS OF UNKNOWN ETIOLOGY*

JOHN H. DINGLE, M.D.,† AND MAXWELL FINLAND, M.D.‡

BOSTON

DURING the last few years, there has been a great deal of interest in the increasing numbers of cases of acute respiratory infection associated with atypical pulmonary lesions in which the common pathogenic bacteria do not seem to play an etiologic role. The vast majority of the reported cases have occurred in adolescents and in young adults. Many of the reports have come from schools,¹⁻⁴ colleges⁵⁻¹⁰ and army camps.^{11, 12} Hospital personnel, particularly interns and nurses, have also featured prominently among the reported cases.¹³⁻¹⁶ Although the mortality in these cases has been extremely low, the period of disability has been quite long. With the accelerated program of studies now in effect in most universities and with the rapid increase in the size of the Army, accompanied as it is by a shorter training period, these cases may constitute a significant problem from the point of view of "time out" from studies or the loss of man-days from training.

The name "virus pneumonia"¹⁷⁻²² has been applied rather loosely to this group of cases and is probably the one most widely employed by practitioners. In most cases, the only justification for the use of this term is the failure to obtain pathogenic bacteria that can be considered etiologic. Individual authors have justified their use of the term on the basis of suggestive histologic findings in the pulmonary lesions,^{17, 20, 22} or on the

results of studies that suggested the presence of filterable agents.¹⁴ Numerous other designations have been used in the description of similar cases. They include "acute influenzal pneumonia"¹¹; "acute pneumonitis"^{2, 3, 12}; "pneumonitis"^{23, 24}; "acute interstitial pneumonitis"⁷; "atypical pneumonia with leukopenia"⁸; "current bronchopneumonia of unusual character and undetermined etiology"¹⁵; "bronchopneumonia of unknown etiology, Variety X"¹⁶; and "atypical bronchopneumonia of unknown etiology."⁴ Most authors have believed that they were dealing with a specific infectious disease that constitutes a new entity.^{7, 13} Reimann¹³ suggested that it be called "acute infection of the respiratory tract, Type A" or perhaps "Type A virus pneumonia" if the virus etiology is confirmed,¹³ or that the more general term "grip"¹⁴ be used. Scadding²⁵ has attempted to classify certain more limited groups of cases according to the character of the pulmonary lesion, particularly according to their distinctive roentgenographic shadows, and has applied the name "disseminated focal pneumonia" to some of them; others he²⁶ called "benign circumscribed pneumonia." In a recent "official statement" to the Surgeon General of the Army prepared by the director of the Commission on Pneumonia, Board for the Investigation and Control of Influenza and Other Epidemic Diseases in the United States Army, it was suggested that, for purposes of classification, these cases be separated from other pneumonias and designated "primary atypical pneumonia, etiology unknown."²⁷

This paper considers the clinical aspects of such cases and the results of attempts to establish the etiologic agent. A review of the cases of pneu-

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, Vol. III, 1942* (Springfield, Illinois: Charles C Thomas Company, 1942. \$5 00).

monia due to known viruses and rickettsias was given in the first section of this report.^{28*}

Primary atypical pneumonia of unknown etiology is, in all probability, not a single disease but a syndrome that may be produced by a number of agents.²⁷ Nor is it a new pathologic syndrome, in spite of the numerous recent reports and the apparent increase in incidence. Positive identification of cases of atypical pneumonia, as reported in the literature, is difficult because no single criterion—clinical or laboratory—characterizes the syndrome. Moreover, clinical criteria for the diagnosis of such related infections as grippe, influenza and bronchopneumonia, which may simulate this disease, vary widely. Despite these difficulties, the entire syndrome can usually be differentiated from similar conditions of known etiology. On this basis, it is apparent that the pneumonia was seen clinically as long ago as 1872,^{29, 30} and a similar pathologic picture was described at about the same time.^{31, 32} With the introduction and use of roentgenography of the chest, further reports appeared, particularly in the literature dealing with tuberculosis and influenza. It seems likely that the disease was prevalent before the pandemic of influenza in 1918 and that it existed in the military forces, where it was given such names as "catarrhal fever" and "soldier's pneumonia."³³⁻⁴² In addition, almost all the reported cases of pneumonia have included a group for which the etiology either could not be determined or was thought to be one of the "higher types" of pneumococci. Clinically, many of these patients did not have typical pneumococcal pneumonia, the course of illness was unaffected by specific therapy, and the outcome was ordinarily complete recovery. Some, if not most, of these patients probably had atypical pneumonia.

Since the papers of Gallagher¹ and Bowen,¹¹ this type of illness has been more carefully differentiated, and cases occurring both sporadically and in small outbreaks have been reported under the variety of names listed above. Recent developments in the knowledge of viruses affecting the respiratory tract have established a preliminary basis for segregation of some of these cases etiologically, but the cause of a large number still remains unknown.

Thus, it is apparent that the characterization of atypical pneumonia is difficult and confusing, and will remain so until the etiologic problem is solved. Diagnosis can now be made only by clinical and radiologic criteria—no one of which is specific—or by exclusion. A description of the character-

istics of the morbid process can only be as reliable as the diagnosis, which likewise is the basic limiting factor in the evaluation of experimental investigation. For simplicity in discussion, primary atypical pneumonia of unknown etiology will be referred to as a disease, although at present it must more accurately be considered a syndrome, possibly with multiple etiologies.

EPIDEMIOLOGY

Occurrence. The full extent of the distribution of atypical pneumonia is not known. Its occurrence has been noted in all parts of the United States,^{1, 3, 6-10, 12-10, 18, 43} in Honolulu,¹¹ in England²³⁻²⁶ and probably on the continent of Europe.³⁹ These reports suggest a widespread distribution, which probably lacks confirmation only because of limited recognition. Rates of attack cannot be determined satisfactorily from the data available in the literature. The disease apparently exists sporadically and in small outbreaks.^{15, 44} Bowen's¹¹ figures indicate a yearly attack rate varying from less than 1 to approximately 6 per 1000 in white troops during a three-year period in Honolulu. The incidence rate at Cornell University was approximately 9 per 1000 for the academic year 1937-1938.⁷ Reimann¹³ observed 25 cases among a hospital staff composed of 813 persons. Daniels⁴ reported 13 cases in a school of about 90 girls during a six-week period—an incidence of almost 15 per cent. Cases of atypical pneumonia have comprised from less than 1 to about 6 per cent of the total admissions for respiratory diseases at different infirmaries and hospitals.^{5, 10-14} It seems likely that the yearly increase in cases recently noted at several clinics may be due, in part at least, to more frequent recognition. It is possible, however, that these are epidemic forms of the disease.

Age and sex. The age distribution in the reported outbreaks has thus far been almost entirely limited to adolescents and young adults. Most of these outbreaks were observed in schools or military posts, where the age of the personnel is limited. The majority of the patients seen in civilian hospitals, however, have been young adults, although the span of age has varied from four to eighty years.^{1-3, 12-10, 23} The limited age distribution may therefore be of significance, although recognition and opportunity for spread may be major factors. Adams^{20, 22} has recently described in infants a somewhat similar virus pneumonia to which adults were apparently not susceptible. This disease, which differs in certain respects from the atypical pneumonias under discussion, is considered below. There is no rec-

*Our attention has been called to the recent report of 2 fatal cases of lymphatic choriomeningitis with pulmonary involvement by Smadel et al.⁴⁵ who isolated this virus from the lungs and other tissues in both cases.

ognized difference between the sexes so far as susceptibility or immunity is concerned.

Season. The seasonal distribution is variable, and sporadic cases apparently occur regardless of season.^{9, 13-16} Many of the reported outbreaks have occurred in the late fall and winter,^{3, 7, 9, 15} although the epidemic described by Reimann and Havens¹⁴ took place between January and May, with the peak of incidence in February. Murray⁹ pointed out that the majority of his cases occurred in November and December, whereas the greatest incidence of the other upper respiratory infections was noted in February and March. McKinlay and Cowan¹⁰ also noted that an increase in upper respiratory infections did not call forth a corresponding increase in atypical pneumonia. These observations, perhaps, tend to dissociate atypical pneumonia from the common cold and other minor respiratory infections.

Spread. Little is known regarding the mode and manner of spread of atypical pneumonia. The general consensus is that it is transmitted by contact but is not highly communicable.^{3, 9, 15, 16} Multiple cases have been seen in members of the same family or of the same household who have had opportunities for close contact.^{4, 7, 13} Smiley and his co-workers⁷ noted that the infectiousness of the disease was apparently not great in the absence of cough. The high incidence of infection in nurses and doctors^{8, 15, 16} supports the theory of contact spread and also suggests that prolonged contact with patients may be necessary. One interpretation may be that the general resistance to atypical pneumonia is high, and as a result a large dose of the infecting agent is necessary to produce the disease. Or the infection may be more widespread than is now generally suspected, many of those afflicted presenting the symptoms and signs of a mild systemic and respiratory disease without demonstrable pulmonary lesions. Those receiving a larger primary inoculum through close contact may be likelier to develop pneumonia. The concept of mild and even inapparent or carrier infections is of considerable interest clinically and epidemiologically because of the necessity of delimiting this disease as a specific entity. A satisfactory laboratory test based on etiology will have to be obtained before this can be accomplished.

Reimann¹³ noted that in a group of 5 patients who had familial contact there were 2 cases of severe infection and 3 of mild disease. In an epidemic among 813 persons at the Jefferson Hospital, he and Havens¹⁴ described 407 cases of respiratory disease. The majority of these were mild infections, and the patients remained ambulatory. A clinical and roentgenologic diagnosis of

acute tracheobronchitis was made in 6 per cent and of pneumonia in 6 per cent. These investigators believed that the patients were ill presumably of the same disease, and further stated, "Cases of the mild form far outnumbered those of the severe form, and for this reason we believe it to be misleading to apply restrictive names indicating special forms of bronchiolitis or pneumonia to cases of the severe form alone, as many have done." Gallagher² also noted 11 cases of mild infection, without pulmonary involvement, that epidemiologically both preceded and followed definite cases with so-called "pneumonitis." Longcope²¹ has observed that patients may apparently contract a severe form of infection from those who have had a mild attack, or that the reverse may occur. It seems likely that such cases as these must be taken into consideration when one is attempting to elucidate the nature and manner of spread of atypical pneumonia.

Incubation period. Reliable data regarding the incubation period of atypical pneumonia are likewise lacking. Reimann and Havens¹⁴ believed that it might be as short as one or two days, but other investigators have estimated the period to be between seven and twenty-one days, or even longer.^{3, 4, 7, 9, 15, 16}

CLINICAL ASPECTS

A clinical description of atypical pneumonia at present must be almost entirely restricted to cases presenting clinical or roentgenologic signs of pulmonary involvement. In spite of the great likelihood that related nonpneumonic or inapparent forms of infection occur, there are no reliable means by which such cases can be differentiated from other minor upper respiratory illnesses. Even in the group showing pulmonary involvement diagnosis may not be easy. From the reports in the literature, it is difficult to accept certain cases as being consistent with atypical pneumonia, although it is entirely possible that the written descriptions convey an impression contrary to that which would be obtained on actual examination of the patient. An attempt is therefore made to present the generally accepted picture of atypical pneumonia; the significant variations that have been reported are noted.

Onset. The onset in the majority of cases is gradual and insidious over a period varying from one day to a week or more. Kneeland and Smetana¹⁵ described the onset as "grippelike." Preceding or accompanying upper respiratory infections have been noted in from 50 to 75 per cent of the cases in some outbreaks,^{2, 3, 9, 10} whereas in others catarrhal symptoms have been rare^{13, 14} and "influenzalike" symptoms absent.

The onset has been described as sudden or abrupt by Daniels⁴ in all his cases, and by Murray⁹ in about one fourth of his cases. It is rarely so abrupt and dramatic as that in pneumococcal pneumonia.

Symptoms. The presenting symptoms are ordinarily quite uniform early in the disease, regardless of the subsequent severity and course of the illness. Fever, cough, malaise, headache and chilliness are almost constant complaints. The temperature may be at any level between 99 and 105°F., or more, but is usually between 100 and 103°F. Cough, at this stage, is very distressing to the patient. It is dry and may occur in paroxysms, which are difficult to control. Substernal pain or soreness and tenderness of the abdominal muscles frequently result from tracheal irritation and cough. The cough may be productive, however, at the onset or early in the course.^{9, 16} The sputum is mucopurulent and may be blood streaked, but is not rusty or suggestive of prune juice. Malaise, aches and pains, and prostration may be out of proportion to the general appearance of the patient. Headache is often severe and is frequently frontal or periorbital, but may be general or localized anywhere. Sensations of chilliness and shivering usually alternate with periods of feverishness, but shaking chills and rigor seldom occur. The throat may be dry or sore before or at the time of onset, but usually sore throat does not persist beyond the first few days of illness. Drenching sweats occur in some cases.^{7, 9, 13, 14} Gastrointestinal symptoms are usually not a feature. Other symptoms, such as stiff neck, vertigo, abdominal distention, dyspnea, cyanosis and mental confusion and disorientation, occur rarely or are seen later in the course of the disease.

Physical signs. Physical examination early in the disease usually reveals little that is abnormal. Fever is almost constantly present, but the majority of the patients do not appear to be so ill as their fever or subjective complaints would warrant. Some patients appear moderately or severely ill, with evident prostration and, occasionally, dyspnea and cyanosis. Aside from pharyngeal injection and, rarely, a palpable spleen,⁹ the examination is negative. The pulse rate ordinarily is within normal limits or low. Respirations are usually normal. Pulmonary signs, if present, are generally limited to fine or medium moist rales occurring late in inspiration.

Laboratory findings. The white-cell count is normal in almost all cases early in the disease. Both leukopenia and leukocytosis are infrequent in the absence of other contributing causes. The sedimentation rate may be elevated, but other laboratory tests are usually negative.

X-ray findings. The first evidence of pulmonary involvement is usually obtained by roentgenologic examination of the chest. Lesions may be apparent on admission and are almost always found within the first few days of the disease. The character, size and location of the lesion are variable.^{4, 9, 11, 15, 16, 23, 26, 47, 48} In the majority of patients, the first change noted is an increase in the size of one or both hilar shadows, followed by an infiltration, which extends outward from the hilum toward the periphery of the lung fields, often in the shape of a fan or wedge, and fades out gradually into the normal lung parenchyma. Origin of the lesion at the periphery of the lung has not been described in typical cases. Most frequently, the lesion is found in one of the lower lobes, but it may occur anywhere. Bilateral involvement is not uncommon, and is found in 20 per cent or more of the cases.⁸ The process may spread to the adjoining lobes and, infrequently, is very extensive, involving all, or almost all, the lobes. Usually, the infiltration is soft, either mottled or homogeneous, and denser near the hilum. It is rarely so dense and circumscribed as that in pneumococcal pneumonia, and seldom does it occupy more than a portion of a lobe.

A number of variations in the radiologic picture have been noted, which may be striking. A fairly well-localized, but not sharply defined, lesion may be found in the lower lobes, particularly in one or the other cardiophrenic angle. The process may be light, diffuse and mottled in any portion of the lung field. There may be multiple small areas of soft infiltration that increase in size and become irregularly confluent; or there may be areas of diffuse, rather coarse mottling in foci varying from 2 to 5 mm. in diameter—the “disseminated focal pneumonia” of Scadding,²⁵ which may be impossible to distinguish from tuberculosis. Kornblum and Reimann⁴⁵ have described the picture of “acute tracheobronchitis,” which they believe represents the same infectious process, as a bilateral increase in the hilar and trunk shadows, with indistinct outlines, soft mottling about the hilum and generally hazy lung fields. Similar findings have been noted in influenza.⁴⁷

Resolution of the process is usually slow, but the shadows may at times be quite transitory.^{26, 46} The process often clears from the periphery of the lesion, which becomes more mottled and then fades. Increase in the size of the hilar shadows may persist for several weeks.

Thus, the radiographic picture, although fairly characteristic, may show sufficient variations to be confused with that of pneumococcal pneumonia, bronchopneumonia, acute bronchitis, tuberculosis, pulmonary abscess, acute bronchiectasis, metastatic

infiltration and, of course, the known virus and rickettsial diseases that involve the lung.²⁸

Course. The course of the disease is generally mild, although cases of varying severity and even fatal ones have been reported.^{13, 15, 16} Therefore, the course will be described separately for mild, moderately severe and severe types; one should bear in mind that the differences are chiefly of degree and not of kind.

Patients suffering from the *mild form* of illness usually show the maximum rise in temperature within three days after onset. The temperature may vary from 99 to 105°F.; it may be sustained but is frequently swinging. Defervescence is usually slow, by lysis, for the next few days. The average febrile period is seven or eight days, although it varies considerably. Allen,¹² for example, reported that 68 per cent of his cases had fever for three to eleven days, whereas 12 per cent were febrile for more than twenty days. Headache and chilliness usually persist throughout the febrile period, and the cough ordinarily becomes productive as the disease progresses. Cyanosis and dyspnea are rare. Malaise, lassitude and fatigue often persist several days or weeks after the acute stage of the illness, whereas sore throat is usually present for only the first few days. Unusual sweating has been noted in certain of the outbreaks.^{9, 13} Bradycardia is common, and the respiratory rate is frequently normal or only slightly elevated.

Physical signs are frequently limited to rales over the involved area, often appearing after three or four days of illness or even longer. In most cases, the rales are fine or medium moist and sticky, and occur late in inspiration, although in some cases they have been described as coarse and explosive.¹⁶ During the later stages, when the cough becomes productive, coarse, wet rales and rhonchi may be present. Dullness may be noted, but it is often slight and little more than an increased sense of resistance. Abnormal breath sounds, increased tactile fremitus and the other signs of consolidation are infrequent, but may be found in from 13 to 15 per cent of the cases.^{2, 3, 9} Spread of the lesion may be detected by physical or radiologic examination and may be associated with exacerbation of symptoms and fever. Other abnormal physical findings are not frequent. Splenomegaly has been noted in a few cases⁹; abdominal distention is unusual. Herpes and pleural effusion are rare.^{9, 15} The ordinary laboratory tests give results within normal limits throughout the course. Ordinarily, the physical signs and objective evidences of illness are gone within two or three weeks after onset, but complete subjective recovery may not occur for four to six weeks.

Complications are not commonly observed, but those described are pharyngitis, tonsillitis, sinusitis, otitis media, pneumonia and empyema due to the

hemolytic streptococcus,¹⁰ urticaria, ulcerations on the palate and persistent productive cough suggesting bronchiectasis.

The *moderately severe cases* differ in no significant particulars from the mild cases, except that the patients feel and look sicker. The progress of the disease may be more rapid. Cough and headache may be more pronounced. Dyspnea and cyanosis may be present. The temperature may persist longer and at a higher level, and may be associated with tachycardia and an increased respiratory rate. Spread of the lesion and relapses may occur. There may be little or no correlation between the clinical severity of the infection and the extent of pulmonary involvement by x-ray or physical examination. Not infrequently, the total white-cell count becomes elevated as the disease progresses, without any apparent evidence of secondary bacterial invasion. Complications may be somewhat more frequent, but are of the same type in these cases as in the mild ones.

In the *severe form*,^{14-16, 21} patients usually have an onset of infection that is similar to that described for the mild cases. The symptoms are more pronounced, however, and the progress of the disease to a severe state may be rapid. Fever, severe headache and persistent cough are the outstanding features. Prostration is marked. Dyspnea and cyanosis are usually present in these cases, and the breathing may be rapid, obstructive and asthmatic. Epistaxis, chills and sweating may occur. Drowsiness, meningismus and coma have been described. The temperature may remain elevated, as in typhoid fever, or may be swinging or "septic." Relapses, giving a biphasic or saddle-back temperature curve, are not uncommon. The pulse may be relatively slow, but more frequently it is rapid and more in proportion to the fever than in the milder cases.

Examination of the chest physically and roentgenologically reveals involvement of variable extent that frequently spreads over a considerable portion of the lung fields. Moist rales and rhonchi are the outstanding features, however, and evidence of dense consolidation is not the rule. Other associated findings are polyarthritis, erythematous rash, pleural effusion, thrombophlebitis, evidence of myocardial involvement and signs of involvement of the central nervous system. These findings are rare, however, and, as mentioned above, it is difficult to be certain that they are related to the same process in the absence of specific diagnostic criteria based on etiology.

Laboratory studies in these severe cases may show a moderate secondary anemia and a gradual elevation of the white-cell count as the disease progresses. The urine may show albumin in proportion to the fever. The sedimentation rate is

elevated.¹⁶ In a few cases, liver damage has been suspected on the basis of slight jaundice, reversal of the albumin-globulin ratio, bromsulfalein retention and a shifting Wassermann reaction.¹⁵

The duration of the acute illness is usually two or three weeks, but it may be six to eight weeks or even longer before complete recovery has occurred and the chest is clear by physical and x-ray examination. Although complete recovery is usual, death may result from the disease itself, from secondary bacterial invasion or from the infection superimposed on pre-existing organic disease. McKinlay and Cowan¹⁰ observed a fatal case complicated by pneumonia and empyema due to the hemolytic streptococcus. In a series of 40 cases described by Longcope,^{10, 21} there were 3 fatal cases, 2 of which were in patients with chronic rheumatic heart disease with mitral stenosis and insufficiency.

Atypical Pneumonia in Infants and Children

Although the outbreaks of atypical pneumonia described in the literature have been almost entirely limited to adolescents and young adults, it seems probable that the disease is not confined to this age group. Several investigators^{12, 23, 26, 46} have described apparently identical illnesses in children between the ages of four and nine years. Recently, Adams, Grier, Evans and Beach^{20, 22} have described two epidemics of respiratory disease in young infants up to thirty-two weeks of age. Low-grade fever, cough, dyspnea and cyanosis were the outstanding features. The only characteristic signs in the chest were widely scattered fine rales. Radiologic examination revealed a patchy infiltration, particularly in the upper lobes. Resolution of the process was slow. The average case fatality rate was 20 per cent, but the rate was especially high in those infants who had been born prematurely (82 per cent). Somewhat similar types of illness have been described previously, usually following measles, pertussis or other conditions.^{17, 18, 49}

PATHOLOGY

Knowledge of the pathology of atypical pneumonia is limited because of the low mortality of the infection. The chief pathological features of the fatal cases reported by Kneeland and Smetana¹⁵ and by Longcope^{10, 21} are those of a patchy, hemorrhagic, interstitial bronchopneumonia associated with acute bronchitis and bronchiolitis. Grossly, there are areas of atelectasis and emphysema, small areas of red or gray consolidation, which in some places have apparently become confluent, and reddened bronchi filled with mucoid or purulent exudate. Microscopically, the alveolar exudate may be hemorrhagic or mononuclear in

some areas, whereas in others there is evidence of organization. The alveolar septums may be infiltrated with mononuclear cells and may later show thickening, with a decrease in the size of the alveolar spaces. The process may be most marked in the alveoli surrounding the bronchi and bronchioles. The walls of the bronchi and trachea show necrosis and infiltration with polymorphonuclear leukocytes, and their lumens are usually filled with exudate containing a predominance of these cells. Edema fluid in the alveoli and frothy pink material in the bronchi have been described in one case,¹⁰ which was complicated by chronic rheumatic heart disease and may have been the result of congestive failure. Necrosis and cellular infiltration of the walls of the pulmonary artery¹⁹ and of its smaller radicles¹⁶ have been noted. Acute splenic tumor and focal hepatic necroses have also been described.¹⁵ No inclusion bodies have been found in these cases.

It is interesting to note the similarity of the above description to those given for bronchopneumonia or "interstitial pneumonia,"^{20, 31, 32} "purulent bronchitis,"³³ influenza, psittacosis and other known virus diseases,²⁸ pneumonia due to the influenza bacillus⁵⁰ and pneumonia complicating measles, whooping cough and other diseases in man and animals.^{17, 49, 51}

Essentially the same pathologic processes were found by Adams and his co-workers^{20, 22} in the lung of infants dying of an acute epidemic respiratory disease mentioned earlier in the paper. In addition, these investigators noted acidophilic intracytoplasmic inclusion bodies in the bronchial epithelial cells. Similar inclusions were found in cells obtained by swabbing of the throats of infected infants, and of control infants and adults having contact with these cases. The presence of inclusion bodies is suggestive evidence of infection with a virus, but conclusive proof of virus etiology can be obtained only by the isolation of the virus and demonstration of its specific relation to the disease. Thus, intracytoplasmic or, more frequently, intranuclear inclusions have been found in the epithelial cells of infants and children following measles, influenza, whooping cough and a number of related infectious and noninfectious processes,^{17, 48, 49} but an etiologic relation has not been demonstrated satisfactorily.

ETIOLOGY

The etiology of atypical pneumonia has not been established satisfactorily. As pointed out above, this clinical syndrome may be produced by a number of known bacteria and viruses, and yet in the majority of the reported outbreaks in which studies were made, none of these agents were identified with the disease.

The usual laboratory procedures have yielded entirely negative results. Blood cultures are ordinarily sterile.¹⁶ Agglutinins are not demonstrable for the bacilli of typhoid fever, undulant fever, tularemia and supestifer infection, and blood smears reveal no malarial parasites.^{8, 16} Cultures of the sputum show the usual throat flora: *Streptococcus viridans*, *Neisseria catarrhalis*, staphylococci, *Str. haemolyticus*, diphtheroids and influenza bacilli.^{1-4, 7, 8, 10, 13-16, 21, 25, 52} Pneumococci have been found in more than half the cases by some investigators¹⁹ and infrequently by others,^{3, 14, 15} but in practically all the organisms are of the so-called "higher types," which are less pathogenic and more commonly found in carriers. Kneeland and Smetana¹⁵ considered the distribution of bacteria present in the respiratory tract of their cases to be essentially the same as that of normal persons. No tubercle bacilli or fungi are demonstrable.^{16, 25} The appearance of hemolytic staphylococci or streptococci in the sputum late in the disease as possible secondary invaders is probably not frequent, since it has been noted in only 3 cases.^{16, 52} Adams and his co-workers^{20, 22} reported no significant bacteriologic findings in their cases in infants.

A number of attempts have been made to isolate rickettsias or viruses from these cases. From Reimann's¹³ cases, Stokes, Kenney and Shaw⁵³ and Francis and Magill⁵⁴ obtained an agent that produced illness and pulmonary lesions in ferrets and mice for a few passages, but then apparently became less virulent and was lost. Neither the influenza nor the psittacosis virus was isolated, and the patients did not develop complement-fixing antibodies for the influenza virus.¹⁴ Enders, Sullivan, Hammon and Meakins⁵⁵ examined blood, sputum and nasopharyngeal washings from 11 of the cases reported by Murray,⁹ but in no case was a virus obtained. Brown⁵⁶ was unable to isolate rickettsias or a virus from various specimens, including pulmonary tissue from the fatal cases reported by Longcope.^{16, 21} As noted above, no inclusion bodies were seen in these cases. Negative results were also obtained in a variety of animals, and in chick embryos with autopsy material from the fatal cases in infants studied by Adams, Green, Evans and Beach,²² although inclusion bodies were seen. Blood and pharyngeal washings from 6 of Daniels's⁴ cases were inoculated by Dyer and Topping⁵⁷ into mice, guinea pigs and chick embryos with negative results.

Weir and Horsfall⁵⁸ have reported the isolation in the mongoose and in chick embryos of a filterable agent obtained from each of 4 patients with "acute pneumonitis." Production of pulmonary

lesions in mongooses was somewhat irregular, since some animals were apparently resistant to infection, and serial passage did not increase the virulence of the agent. By a rather laborious passage technic, it was found that the agent, when mixed with convalescent serums of the patients, produced a lower percentage of pulmonary lesions in the mongoose than when acute serums were similarly employed, indicating the development of neutralizing antibodies. A large variety of animals, including monkeys, were resistant to inoculation with the original material from the patients, as well as with pulmonary tissue from the infected mongoose. The agent was apparently not related to other known viruses producing respiratory disease.

Further work is necessary to clarify the etiologic situation in atypical pneumonia. Until this has been accomplished, diagnosis of the disease will remain uncertain. Differentiation should be made as completely as possible on the basis of laboratory tests to exclude the known viruses that can cause the same clinical picture, such as those of influenza A and B, psittacosis, meningopneumonitis,^{28, 59} ornithosis and rickettsias. Other conditions such as tuberculosis, typhoid fever, undulant fever, pneumococcal pneumonia, coccidioidomycosis, bronchiectasis, cancer, pulmonary infarction and atelectasis, must, of course, be considered in the differential diagnosis.

TREATMENT AND PREVENTION

The treatment of atypical pneumonia at present is entirely supportive or symptomatic, since no specific measures are known. The diet may be unrestricted or determined by the patient's appetite. The fluid intake, either orally or parenterally, should be maintained at 3000 to 4000 cc. per day or more during hot weather. Adams and his co-workers²² have stated, however, that infants with "primary virus pneumonitis" do not tolerate parenteral fluids well. Opiates, particularly codeine sulfate in $\frac{1}{2}$ -gr. or 1-gr. doses, are of value for cough, headache and generalized aching, but suppression of these symptoms may be difficult. Expectorants may be helpful when sputum is scant. Steam inhalations, with or without tincture of benzoin, or an increase in the humidity of the ward may give some relief. Abdominal binder and an ice cap may also be helpful. Reimann and Havens¹⁴ recommend that acetylsalicylic acid, acetophenetidin and aminopyrine be avoided because of the diaphoretic action of these drugs, particularly in cases in which sweating is an annoying symptom of the disease. Oxygen therapy, a trachea or a nasal catheter being employed, usually relieves dyspnea and cyanosis. Postural drainage may be of value if the cough becomes productive.

of large amounts of sputum in the later stages of illness. Sprays or gargles of physiologic saline solution or weak sodium perborate solution may be employed, and a spray of 1 per cent aqueous solution of ephedrine may be used to relieve nasal obstruction. Enemas should be employed as indicated.

Transfusions have been recommended^{8, 22} Kneeland and Smetana¹⁵ have given a transfusion from a convalescent donor in 1 case, but the value of this specific therapy has not yet been established. The various sulfonamide drugs have been used in a considerable number of cases,^{3, 4, 14, 10, 22} without any significant effect on the course of the disease. Indeed, in some cases, the reactions to these drugs have materially increased the discomfort of the patients.¹⁴ Pneumococcal antisera have been tried in a few cases, without evident success.¹⁴ In most cases, a prolonged period of convalescence is required. Complications should be treated as indicated.

Only general preventive measures are available in attempts to stop the spread of atypical pneumonia. The infection is apparently not highly communicable, but the large number of cases occurring in medical personnel caring for these patients indicates contact spread, possibly by droplet infection. Strict isolation of the patients is recommended.^{14, 21} Masks and gargles may be of value.⁶⁰ Prevention by immunization must await the isolation of the etiologic agent.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28361

PRESENTATION OF CASE

A forty-year-old man was admitted to the hospital because of bouts of abdominal pain.

Five months before admission, the patient experienced a sudden attack of pain without anorexia or nausea, sharply localized to the right lower quadrant. This episode lasted three days. No change in bowel habits had occurred, and on examination, there was only mild tenderness in the right lower quadrant. A month later, similar symptoms recurred, and an "infected appendix" was removed at a community hospital. At operation, an inflammatory mass of undescribed size was attached to the ileum several inches from the ileocecal valve. Following this, the patient made an uneventful recovery. Five weeks later, symptoms recurred, but at this time, the patient complained of generalized gas pains and soreness in the epigastrium. These were relieved by an enema, but recurred once during the succeeding month with an associated left-lower-quadrant pain. This time, relief was obtained from a topical application of heat. No changes in stool habits or characteristics were noted.

The family and past histories were irrelevant.

Physical examination revealed a rather thin man in no obvious distress. The heart and lungs were normal. A firm, movable "egg sized" tender mass was felt in the right lower quadrant several inches to the side of the umbilicus. Rectal examination was negative.

The blood pressure was 125 systolic, 80 diastolic. The temperature was 98.6°F., the pulse 90, and the respirations 20.

Examination of the blood revealed a hemoglobin of 14 gm., and a white-cell count of 9800 with 88 per cent polymorphonuclears, 8 per cent lymphocytes, 2 per cent monocytes and 2 per cent eosinophils. The blood Hinton reaction was negative. Urine and stool examinations were negative.

A barium enema passed to the cecum without delay and entered the terminal ileum. Approximately 6 cm. from the ileocecal valve, there was a localized area of ulceration on the lateral wall of the terminal ileum, with rather sharp margins. In addition to the area of ulceration, a soft-tissue mass appeared to be pressing into the

lumen of the bowel. There was a moderate amount of mucosal swelling. The ileum proximal to the lesion was not dilated. A single diverticulum was seen in the midtransverse colon.

Operation was performed on the ninth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD HAMLIN, JR.: I think we had better start with the x-ray films.

DR. AUBREY O. HAMPTON: The radiologist can not often give a report so definite as this, but these films show why he was so certain that the ileum was ulcerated—there is a notchlike projection here simulating a gastric ulcer. It is a deep ulcer, 1 cm. in diameter, and there is an area of rigidity around it that might also be shallowly ulcerated, 3.5 to 4 cm. in width. The reason the radiologist said that there was a mass pressing into the ileum is that there do seem to be a large number of mucosal folds in the area of this lesion which are not exactly normal.

DR. HAMLIN: Could the effect be produced by rigidity of the bowel?

DR. HAMPTON: I think the bowel must have been rigid near the ulcer over an area about 3 cm. in length.

DR. HAMLIN: The patient complained of intermittent pain, some of which might be classed as a local peritoneal irritation, some of which was quite likely due to low-grade intestinal obstruction, and some of which I cannot account for. I should rather like to know—he is described as a thin man but we are not told whether he had loss of weight or increased fatigability—whether or not this was a chronic lesion that had produced effect. The examination tells us nothing more than that there was a mass in the right lower quadrant. The laboratory data reveal nothing of any significance except that there was no evidence of real acute inflammation, although perhaps one could call this a low-grade inflammatory process. The written x-ray report puzzled me more than anything else. One other thing that bothered me was the description of the inflammatory mass noted at previous operation at the time of appendectomy because of the use of the word "attached." It sounds rather like a tumor that was protruding from the wall of the intestine.

Several conditions might have been responsible for this lesion. The first thing I thought of was the question of foreign body. A foreign body which impinged on the mucosa of the bowel and became imbedded, could produce such a low-grade inflammatory process, although Dr. Hampton's comments make it seem rather less likely. The chief objection is the elapsed period of five

months since the onset of symptoms, which is rather a long time to associate with a foreign body in such intimate contact with the bowel.

The patient had a tumor. Could the tumor have been neoplastic? The carcinomas and carcinoids of the small bowel are rare. The one or two that I have seen certainly produced no picture such as this. They are mostly annular and constricting and much more likely to cause obstruction than ulceration of this nature. The one tumor that seems most likely to produce a picture of this sort rather than any other is lymphoma, and that I cannot exclude. One would think that lymphoma would be more likely to cause a secondary anemia and blood in the stools, which this man did not have.

A Meckel's diverticulum containing gastric mucosa occurred to me as a possibility. The lesion is certainly rather closer to the cecum than one would expect, and a study that Wallace¹ made in this hospital revealed that when the symptoms from a Meckel's diverticulum could be attributed to the presence of gastric mucosa they resulted before the age of twenty, and this man was well beyond that. Accordingly, we can probably exclude any effect of a Meckel's diverticulum.

When one considers the diseases of the ileum, one immediately thinks of ileitis. Could this have been an atypical form of regional ileitis? Crohn and Berg² state that blood almost invariably is noticed in the bowel movements. However, of the 33 cases of regional ileitis in the series reported by Warren and Miller³ in this hospital, only 2 showed blood in the stools. Diarrhea is one of the most important symptoms of regional ileitis; yet in this same series, 6 patients had no evidence of diarrhea when the diagnosis of ileitis was made. Obstruction is not an obstacle, because in studies of ileitis there may be no x-ray evidence of obstruction such as one would expect from constriction of the inflammatory lesion. The one factor that is perhaps more of an obstacle than any of the others is that fistulas did not result following the appendectomy. All the fistulas that have been seen in this hospital in cases of regional ileitis have resulted from operation.

There are several other lesions or diseases that might possibly produce this picture, most of which are rare and are not worth the time to discuss. I cannot exclude a lymphoma or an atypical regional ileitis, and of the two I should favor the latter.

DR. HAMPTON: I was just about to say that I do not believe we have seen anything similar to this in regional ileitis. A local single ulceration would be most unique, I should think; and then

it does have the picture of a tumor by x-ray—the shelllike margin around the area of stiffening. This penetrating ulcer simulating a gastric ulcer is the part that we did not like because we had not seen such a picture. It seemed as if there might be a “nigger in the woodpile,” but I think the diagnosis on x-ray study was lymphoma.

A PHYSICIAN: What would you say about carcinoid?

DR. HAMPTON: It does not produce ulceration.

DR. TRACY B. MALLORY: I should emphatically say that we have never seen ulceration with carcinoid in the ileum. On the other hand, carcinoid frequently involves regional lymph nodes and would account for pressure from an extrinsic lesion in addition to signs of intrinsic mass.

DR. LELAND S. MCKITTRICK: We thought there was a possibility that there was no ulcer—in other words, that this was infolding of the mucosa.

DR. HAMPTON: No one suspected that. We thought it must be ulcerated.

DR. MCKITTRICK: Just to be sure of the written impression of the X-ray Department, it says: “This can be either inflammatory process or tumor. If tumor is the cause, the most likely possibility would be carcinoma or carcinoid.” That may not represent the impression of the X-ray Department, but that is the written interpretation.

DR. HAMPTON: That is the impression of an individual. The majority of the department staff did not agree with him.

DR. MCKITTRICK: When this man was sent to me, I thought he had regional enteritis from the story. I cannot find my preoperative diagnosis, and I am not absolutely sure of the diagnosis we operated under, but I think it was carcinoma even though the location was unusual. There is no reason why it could not occur there, and the x-ray picture was entirely consistent, as was the clinical story. The patient did have a lesion that was perfectly characteristic of a carcinoma—a firm hard indurated mass, classic in every way. The unusual part about it was the large mass of non-broken-down lymph nodes extending along the root of the mesentery. Further exploration showed that the liver and spleen were normal; there was nothing else within the abdominal cavity that I could find. We did a right colectomy.

A PHYSICIAN: Including the terminal ileum, of course?

DR. MCKITTRICK: Yes; the terminal ileum and the right colon around to the midtransverse colon were removed. That was the only way we could include the lymph nodes at the root of the mesentery without interfering with the blood supply.

CLINICAL DIAGNOSIS

Carcinoma of terminal ileum?
Terminal ileitis?

DR. HAMLIN'S DIAGNOSIS

Regional ileitis?
Lymphoma?

ANATOMICAL DIAGNOSIS

Malignant lymphoma, lymphoblastic type, of ileum.

PATHOLOGICAL DISCUSSION

DR. MALLORY: We were puzzled by this specimen when it came to the laboratory. When it was opened, there was an ulcerative tumor of the bowel looking like carcinoma, and a mass of lymph nodes in the mesentery, some of them matted together. Cutting across this mass of nodes, we found them to consist of soft pinkish tissue that showed no signs of necrosis or breaking down, so that the nodes were very unlike carcinoma and very suggestive of lymphoma. On the other hand, our experience with lymphoma in the bowel is that the regional lymph nodes are very seldom involved even when grossly enlarged. They ordinarily show simple hyperplasia and no lymphomatous infiltration, whereas it was obvious that these nodes were neoplastic. Microscopic examination showed that it was lymphoma of an undifferentiated lymphoblastic type, and the same picture was present both in the bowel wall and in the regional lymph nodes.

Since operation, this patient has been given intensive x-ray treatment. I do not know whether the tumor has recurred.

DR. MCKITTRICK: I heard from the patient's physician recently. The patient was reported to be doing well six months after the operation.

DR. MALLORY: A significant proportion of these lymphomas of the bowel, of course, do remarkably well after resection. We have cases that have run seven, nine and eleven years after resection, and they are therefore well worth operating on.

CASE 28362

PRESENTATION OF CASE

A forty-four-year-old lumber salesman was admitted to the hospital because of periumbilical pain, nausea and vomiting.

Ten weeks prior to admission, on the morning following an evening of heavy eating, he suffered the first attack of biliousness and diffuse intermittent abdominal ache, nausea and vomiting. His physician treated him with belladonna and paregoric, and the symptoms disappeared after five days. The patient was well until ten days before admission, when similar symptoms occurred, and several days later he noted for the first time continuous aching pain in the left side of the abdomen. This was partially relieved when he vomited some "dark fluid."

X-ray studies at another hospital were said to have shown partial obstruction in the midportion of the small intestine, esophageal varices, a small liver shadow and diverticula in the lower portion of the descending colon. After these studies were made, the patient improved and remained well until twenty-four hours prior to admission to this hospital. At this time, two or three hours after eating, the usual symptoms of biliousness, nausea and abdominal ache recurred and were relieved by vomiting. The patient was symptomless on the day of admission. The vomitus had never contained blood, and there had been no changes in the stool characteristics.

The family history was irrelevant.

At seventeen years of age, the patient had peritonitis secondary to a perforated appendix, and this required drainage for seven weeks. Following this, he developed phlebitis in both legs, which had intermittently been swollen ever since. Thirteen years before entry, a sore left leg and hip developed. Soon after this, the patient had an attack of severe chest pain and dyspnea, interpreted as pulmonary infarction. The cardiorespiratory history was otherwise irrelevant.

The patient was said to have consumed four or more highballs each day. His diet included meat, milk and vegetables; however, he usually ate only one meal a day.

Physical examination revealed a well-developed and well-nourished man in no discomfort. Examination of the heart and lungs was negative. The veins over the upper and lower abdomen were prominent. No abdominal masses were felt, and there was no tenderness. Rectal examination was negative. There was slight edema of the left leg, and pigmentation of both lower legs.

The blood pressure was 118 systolic, 68 diastolic. The temperature was 99°F., the pulse 89, and the respirations 20.

Examination of the blood revealed a red-cell count of 4,000,000 with a hemoglobin of 78 per cent, and a white-cell count of 9500. Examination of the urine was negative.

On the second hospital day, soon after a meal of toast and coffee, the patient noticed the onset of slightly crampy midabdominal pain, which increased in severity during the day. The patient retched but was unable to vomit. Physical examination at this time was negative.

That evening, he vomited several hundred cubic centimeters of slightly green, watery material and obtained immediate relief. There was moderate diffuse tenderness, maximum to the right of the umbilicus, and spasm of the entire abdomen.

The patient vomited several times during the next day. The white-cell count was found to be 40,700 and, five hours later, 48,000. At this time, there was definite tenderness in the right upper quadrant, and operation was immediately performed.

DIFFERENTIAL DIAGNOSIS

DR. REGINALD H. SMITHWICK: So far as I can see, there was no opportunity to take any x-ray films on this patient before he was operated on, at least in this hospital.

The picture given by the history is that of a well-nourished, middle-aged man who, aside from slight secondary anemia, appeared to be in good condition on entry to the hospital. The past history is important in that he had an operation for appendicitis, with drainage, twenty-seven years previously. There is evidence that this was followed by a deep thrombophlebitis, with exacerbation four years later. This might be the explanation for dilated veins over the lower chest and abdomen rather than cirrhosis of the liver resulting from indiscretions of eating and drinking. In any event, the relation of either an old deep thrombophlebitis or cirrhosis to the present illness is not clear.

The present illness consisted of four attacks of crampy, periumbilical pain, associated with nausea and vomiting over a ten-week period, the first lasting five days and the second a shorter period—being followed, however, by less severe, but rather persistent abdominal discomfort. The third attack was sudden and severe but of short duration, and the fourth was sudden in onset, with increasing severity, persistent nausea, tenderness, spasm and a striking rise in the white-cell count. No mention is made of distention or abnormal peristalsis. The nature, location and severity of the pain, coupled with the information from the x-ray examination elsewhere revealing partial obstruction, suggest that the lesion was located in the small intestine.

Other conditions that might possibly cause these symptoms are pancreatitis, disease of the biliary tract, with subsequent rupture of the gall bladder, possibly a perforated peptic ulcer, diverticulitis with perforation and appendicitis. Presumably, the appendix was removed twenty-six years

previously, although one cannot be certain that that was so. Diverticulitis with perforation is rare, except in the sigmoid. No mention is made of fever, which should be considerable if the cause of the symptoms at the time of the operation was primarily an inflammatory process, although it is possible that peritonitis was present at the time of operation.

The most probable diagnosis is obstruction of the midportion of the small bowel, associated with interference of the blood supply. Mesenteric thrombosis might cause such a picture, but the pain is likelier to continue and does not explain four attacks in ten weeks, with spontaneous recovery from the first three. In view of the previous operation, partial obstruction from an adhesive band culminating in obstruction should be placed first as the cause of this man's difficulties. The symptoms, however, could be equally well explained by recurring intussusception related to tumor, polyp or stricture of the small bowel, resulting in necrosis of the invaginated bowel.

DR. LELAND S. MCKITTRICK: Do you exclude an acute pancreatitis? You passed over that very quickly, Dr. Smithwick. Do you believe it is usually so easy to rule it out in such a case?

DR. SMITHWICK: It seems to me that, with an acute pancreatitis, it is unusual to have so many attacks as this man had, although we do know that it can be recurrent. Acute pancreatitis simulating small-bowel obstruction, I believe, was the first disease mentioned in the differential diagnosis; it should be included. I should expect that more would have been said regarding the general serious condition of the patient, with more evidence of shock and collapse, and I should not expect the white-cell count to be so elevated as this man's was. It would be much lower in acute pancreatitis, and there would be a good deal more evidence of collapse than I gather from the clinical description in this case. I think acute pancreatitis is a very definite possibility, but I do not put it first.

DR. TRACY B. MALLORY: Does anyone want to hazard an opinion on the relation of the four highballs a day to the esophageal varices? That is a rather crucial figure.

DR. MCKITTRICK: I suppose that would depend on the highballs. Many people would believe that four a day would do it.

DR. AUBREY O. HAMPTON: They said that he had a small liver, did they not?

DR. SMITHWICK: I was rather inclined not to lay much stress on that because it seemed to be information that was obtained elsewhere and was not confirmed by evidence accumulated during the present illness.

DR. MCKITTRICK: I rather had the impression that obstruction had a much more abrupt and

more positive onset than this. I should be a little hesitant to expect strangulative obstruction, because of the past history. Also, the story of the last month alone would not fit into my concept of strangulated small-bowel obstruction, but I am probably being educated.

DR. SMITHWICK: So far as I can estimate from the history, in the course of twenty-four to thirty-six hours, this man passed from a healthy person to one who was desperately sick, with no mention of fever or other evidence of an inflammatory process. That seems quite abrupt and severe to me.

DR. MALLORY: The temperature on the first day was 99.5°F., and on the second 98°F.

DR. SMITHWICK: With increasingly severe pain of rather sudden onset, I gather from the description of the periumbilical crampy midline abdominal pain.

DR. MCKITTRICK: But not bad.

DR. SMITHWICK: Not bad at the moment it started, but increasingly severe, followed by generalized tenderness and spasm.

DR. REED HARWOOD: Did you ask if the esophageal varices and small liver could be linked with the present symptoms?

DR. MALLORY: No; but I should be interested if anyone had a theory by which they could be explained. What should you say, Dr. Hampton, about the reliability of the radiologist's observation of varices?

DR. HAMPTON: If the examination is carried out in a Grade A hospital by a Grade A man, the observations should be very accurate. I wager that this patient had cirrhosis of the liver, because I know who made the examination.

A PHYSICIAN: Dr. Fuller Albright had a patient with four attacks of pain simulating gall-bladder disease and various other things who finally had a severe venous thrombosis of the small bowel.

DR. SMITHWICK: I was not aware that cirrhosis of the liver ever resulted in mesenteric venous thrombosis. If so, that would be a likely sequence of events in this case.

PREOPERATIVE DIAGNOSIS

Gangrene of bowel.

DR. SMITHWICK'S DIAGNOSIS

Obstruction of midportion of small bowel, with occlusion of its blood supply.

ANATOMICAL DIAGNOSES

Mesenteric and portal thrombosis, recent.

Venous infarction of small intestine, acute.

Thrombosis of splenic vein, old.

Thrombosis of femoral and popliteal veins, old, bilateral.

Esophageal varices.

Splenomegaly, slight.

Peritonitis, acute.

Operative wound: appendectomy.

PATHOLOGICAL DISCUSSION

DR. MALLORY: This patient was explored. When the abdomen was opened, the operator felt a mass that was surrounded by omentum. On peeling back the omentum, he found that the mass consisted of loops of discolored small intestine, about 150 cm. in length and matted together by fibrinous adhesions. All the veins in the mesentery leading from these loops were thrombosed. The surgeon, who also examined and felt the liver, reported that it was small and that it was finely granular and tough. He noted a very hard cord, which extended from somewhere near the hilum of the liver across the abdomen in the direction of the spleen, and suggested an old thrombosis of the splenic vein.

At autopsy, two days later, the latter observation proved to be entirely correct. There was complete obliteration of the splenic vein, obviously going back many years; it was completely organized and partially recanalized. The spleen was fibrotic, but not much enlarged. There were esophageal varices, but the liver seemed entirely smooth and softer than normal; microscopically, there was no cirrhosis. The acute thrombotic process in the mesenteric veins had, in the intervening two days, spread to involve the entire portal system. Every peripheral branch of the portal vein was thrombosed, as was the main portal vein, and the thrombi extended well up into the portal radicals of the liver. There were old and dense fibrous adhesions about the cecum in the region of the appendix, but none of the adhesions could have obstructed any loop of small bowel, so that we have nothing at autopsy to account for the intermittent attacks except the thrombotic process; accordingly, I think we must assume that the thrombosis had occurred in stages and did account for the recurring episode.

DR. MCKITTRICK: Warren and Eberhard* some years back, from a study of venous mesenteric thrombosis, concluded that one could have recurring episodes without necrosis of the bowel, many times culminating in episodes of this kind. The recurring multiple episodes in the past are entirely consistent with it.

DR. MALLORY: I had forgotten that. I suppose that it could occur with venous thrombosis but probably never with the arterial type of mesenteric thrombosis.

*Warren, S., and Eberhard, T. P. Mesenteric venous thrombosis. *Surg., Gynec. & Obst.* 61:102-121, 1935.

INDUSTRIAL MEDICINE IN MASSACHUSETTS

THE announcement of the Committee on Industrial Health that appears elsewhere in this issue of the *Journal* focuses attention on the medical aspects of a dislocation in civil life that is of growing importance. The industrial expansion of the Nation is now of such proportions that it is said to be creating urgent problems in many areas. As yet, no one has actually conducted a survey with sufficient care to give an accurate picture, but it is well known that whole cities and towns for the sole purpose of wartime production are rapidly springing into existence. How quickly and how completely they may be provided

with the civilized accoutrements of the older cities and towns in these days of shortages and priorities is an open question. Already, established cities and towns are learning that they must sacrifice many of the things they formerly considered essential, and these sometimes include medical services. For example, the Procurement and Assignment Service has not hesitated to classify the only physician in a small town as available when such a town is relatively close to others from which doctors can be obtained when needed. This and other comparable privations are beginning to create an appreciation of the immensity of the task. To what extent industrial demands, over and above the tremendous military needs, for medical service will still further deplete civilian resources remains to be seen, but it is both prudent and timely that steps are being taken to prepare for whatever dislocation becomes necessary.

In Massachusetts, the natural geography is such that large areas cannot be altogether remote from medical and hospital services. There are a larger number of both physicians and hospital beds per unit of population than in most other sections of the country, and expansion generally consists in the enlargement of previously existing plants or facilities. Furthermore, the State Department of Labor and Industries is well organized and alert, and its Division of Occupational Hygiene is nationally recognized as a leader in industrial medicine. And, finally, certain members of the State Department of Public Health are especially interested in the potentialities of industrial health. In other words, Massachusetts appears to be in a position to solve whatever problems arise, and to do this with already existing machinery. If so, she will be more fortunate than other states, where the resources are more meager and the load relatively greater.

During the early days of the late depression, President Ernest M. Hopkins, of Dartmouth College, insisted that times of stress and change were times of opportunity for those who could foretell and foresee the trends of the future. Not only did this prove to be so, but many who set their courses, not by foreseeing the future, but by mere

expediency, lived to reap the benefits of currently changing fortunes. In ordinary times, an expanding and medically minded industry would reach for a young physician—a man who could grow and mature with the business. Today, however, the opportunity is open to all. It is likely that those who have done best in private practice will do best in industrial practice, and this is fortunate because in Massachusetts the greatest opportunity lies in serving small plants, in which three quarters of the workers of the State are employed. The medical service for these small plants is almost certain to develop as a part-time activity of the practicing physician, rather than as a full-time assignment. This circumstance also places industrial medicine where it belongs—not in the group of specialties, but in the group of activities that constitute the general practice of medicine and surgery.

VIRUS PNEUMONIA AND ORNITHOSIS

THE atypical pneumonias of varying severity that fail to yield significant bacteriologic agents and also fail to show the characteristic favorable response to sulfonamide drugs continue to be a challenge to physicians and laboratory investigators. At present, the group may be said to constitute a fairly well-defined clinical syndrome. The meager positive results of laboratory studies, however, have already pointed to the diversified character of the etiologic agents in cases that present very similar clinical findings. The situation is probably analogous to that found in primary lobar pneumonia, which is now known to consist of a group of specific infectious diseases caused by many organisms, of which certain types of pneumococci are the most frequent.

The possible significance of the rickettsia of Q fever and of the virus that Weir and Horsfall encountered when they used the mongoose for the study of materials from human cases has already been discussed in the *Journal*.^{*} Intensive work on

this problem is continuing in a number of laboratories throughout the country, and also by groups of investigators in the Army and Navy. The present status of the problem is summarized in this and the preceding issue of the *Journal*.

Two important points brought out in these reports are worth emphasizing. The first concerns terminology. The diagnosis "virus pneumonia" is now widely used both in verbal discussions and in many written reports, in spite of the failures to demonstrate filterable viruses in almost all the cases so labeled. Many writers, to avoid this possibly misleading designation, have resorted to the use of a number of terms, each of which emphasizes some clinical, roentgenologic or, sometimes, pathologic feature of the disease. For purposes of classification, however, there are serious objections to such terminology. The designation recently recommended to the Surgeon General for use in the United States Army is, "*primary atypical pneumonia, etiology unknown*," and this seems to be the most suitable one suggested thus far. It implies that an earnest effort has been made to rule out the known etiologic agents, particularly bacteria. It also implies that the known nonbacterial causes of similar respiratory infections, such as influenza, psittacosis and Q fever, have been considered and that they were either ruled out or thought to be unlikely causes on clinical or epidemiologic grounds.

The second point of interest is the increasing number of reports of the finding of a psittacosis-like virus in some cases of this group, as well as the association of these cases with pigeons and domestic fowl. The studies of a number of workers, including Meyer, Pinkerton, Francis, Eaton and their collaborators, have indicated that the virus concerned is very widespread among the pigeons in this country wherever it has been sought. It has been isolated from a significant number of birds in many pigeon lofts, and serologic studies have indicated very widespread latent and subclinical infection. Furthermore, evidence of infection has been found in the pigeons

^{*}Editorial. Virus pneumonia and Q fever. *New Eng. J. Med.* 224:36, 1941.

in Central Park and in other parts of New York City.

Cases of atypical pneumonia, clinically similar in all respects to those described by many writers, have occurred in pigeon breeders and also in persons having contact with ordinary street pigeons. Serologic evidence of infection has also been found in many pigeon breeders who have had no clinical symptoms. Infections, both latent and manifest, have been observed in barnyard fowl, including chickens, ducks and turkeys, but not in wild birds, and cases ascribable to contact with sick fowl have also occurred.

Meyer has suggested that such infections be called "ornithosis" and that the atypical pulmonary infections associated with them be termed "ornithotic pneumonia." Thus, another group of cases of atypical pneumonia has been removed from the category of "etiology unknown." The diagnosis may be established by the demonstration of the virus by means of mouse inoculation of sputum or lung material obtained at the height of the disease; or infection with the virus may be demonstrated by an increase in the titer of antibodies by complement-fixation tests for the virus during convalescence. There are some difficulties involved in both methods because of the close immunologic relation between the psittacosislike virus of pigeons and certain naturally occurring viruses of mice, as well as the virus of lymphogranuloma venereum. Since subclinical infection with the last virus has been demonstrated recently, this difficulty is more than merely theoretical.

It should be borne in mind, however, that the number of human cases of atypical pneumonia in which the pigeon virus has been demonstrated either by direct isolation or by immunologic tests is still very small in comparison with the number of cases in which it has been sought. In many, if not most, proved cases, a history of contact with pigeons, and often with sick ones, could be elicited. In the great majority of cases of characteristic atypical pneumonia, the etiology still remains unknown. It is hoped that the intensive studies now

in progress will remove a greater proportion of these cases from this category and place them in the group of cases with known etiology.

MEDICAL EPONYM

VON RECKLINGHAUSEN'S DISEASE

This disease forms the subject matter of a monograph by Friedrich Daniel von Recklinghausen (1833-1910), professor at Strassburg, entitled *Über die multiplen Fibrome der Haut und ihre Beziehung zu den multiplen Neuomen* [Multiple Fibromas of the Skin and Their Relation to Multiple Neuromas] (Berlin, 1882), which appeared as a part of the *Festschrift* commemorating the twenty-fifth anniversary of the foundation of the Pathological Institute in Berlin and dedicated to Rudolf Virchow. A portion of the translation follows:

From the results of these studies, I may assert that these little tumors are fibromas, which are formed in the small nerves of the skin after the same fashion as the fibromas in the larger trunks. . . . In respect to their origin, the multiple, soft fibromas of the skin have arisen from neuromas, hence *neuromatous fibromas* or *neurofibromas*.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON INDUSTRIAL HEALTH

Following the announcement that called attention to the distribution of the *Manual on Industrial Health for Defense* in the July 30 issue of the *Journal*, the Committee on Industrial Health received several inquiries from physicians seeking openings in industrial medicine. Because the committee had no ready method of meeting these inquiries, on August 17, it voted to "constitute itself as an agency to gather what information it can concerning doctors who may be available for industrial work and also information concerning possible placements for such doctors, working, of course, in close co-operation with the Procurement and Assignment Service and with due regard for other than industrial need for medical service."

If this function is to be developed, it will be necessary for the committee to possess certain information concerning physicians who are ready to undertake industrial practice. The committee is therefore preparing a registration form that will be forwarded to any Massachusetts physician who wishes to record himself or herself as a candidate

for industrial assignment, as well as to state the conditions under which he or she would be willing to accept such an assignment. The committee may be addressed for this purpose at 8 Fenway.

DWIGHT O'HARA, *Chairman*

COMMITTEE ON MATERNAL WELFARE

CASE HISTORY: GONOCOCCAL SEPTICEMIA, PELVIC PERITONITIS AND THROMBOPHLEBITIS, FOLLOWED BY LAPAROTOMY AND DEATH

In a twenty-nine-year-old primipara who had been treated intelligently and adequately during her pregnancy, labor was induced by rupture of the membranes two weeks from term because of mild toxemia, a blood pressure of 160 systolic, 110 diastolic, and slight albuminuria. The past history was irrelevant. Labor started immediately after the membranes had been ruptured and progressed normally to full dilatation. The patient was delivered by low forceps because of the prolonged second stage and because of maternal fatigue. The third stage was complicated not by hemorrhage but by the fact that the placenta did not separate. During the first twenty-four hours after delivery, several 1-cc. doses of pituitary extract were given to stimulate separation of the placenta. Because this did not accomplish separation, the uterus was invaded manually under very strict asepsis, the line of cleavage between the placenta and the uterine wall readily found, and the placenta and membranes manually delivered intact. There was no hemorrhage during or following this procedure. A chill followed within the first twenty-four hours after delivery of the placenta, a septic temperature developed, and in spite of repeated transfusions and chemotherapy the patient died two weeks later. Gram-negative intracellular diplococci were found in a smear from the cervix, and repeated gonococcal-fixation tests were reported positive. Two days before death, a laparotomy was undertaken for the purpose of draining a pelvic abscess. Autopsy showed general septicemia, pelvic cellulitis, acute pelvic peritonitis, thrombophlebitis of the right common iliac vein and an infarct in the right lung.

Comment. The operative conduct of this case cannot be criticized. Induction of labor by rupture of the membranes during the last month of pregnancy, in the presence of increased blood pressure and albuminuria, is certainly advisable treatment. The fact that labor immediately followed rupture of the membranes shows that the cervix was favorable for induction. The delayed second stage had no necessary connection with this induction. The question of leaving a placenta in

situ for twenty-four hours or longer after the birth of the baby is a problem that is treated differently in various clinics. In the absence of hemorrhage, it should certainly be safe to leave the placenta as long as it was left in this case before manual removal is attempted. It is logical to conclude that in patients of this sort who do not bleed after delivery the placenta has remained entirely attached. It is in cases in which partial attachment and partial separation occur, accompanied by free hemorrhage, that the placenta must be immediately attended to. In this case, the uterus was invaded under strictest asepsis for the purpose of making a diagnosis. This might have been a completely adherent placenta and one that was an accreta, which could not have been removed manually. The diagnosis of this condition can be made only by intrauterine manipulation. Had placenta accreta been diagnosed, the treatment would have been transfusion and hysterectomy. In this case, since there was apparently no bleeding during or following the operation and since the line of cleavage was easily recognized, the placenta was a mildly adherent one. Because gonococci were isolated in a smear from the cervix and gonococcal-fixation tests were positive during convalescence, the bacteriologic cause of the infection is demonstrated beyond argument. The trauma of removing this placenta may well have been a contributing factor. There is nothing to commend the laparotomy that preceded this death by two days. Had a pelvic abscess been apparent, it should have been drained posteriorly.

DEATH

JACOBY — RUDOLPH JACOBY, M.D., of Newtonville, died August 20. He was in his fifty-third year.

Born in Newburyport, Dr. Jacoby received his degree from Boston University School of Medicine in 1911. He was professor of dermatology and syphilology at Boston University School of Medicine, and was a member of the American Academy of Dermatology and Syphilology and the New England Dermatological Society, and a fellow of the Massachusetts Medical Society and the American Medical Association.

His widow and two sons survive him.

MISCELLANY

NOTE

The Medical Library Association held its forty-fourth annual meeting in New Orleans on May 7-9, 1942. The officers elected for the coming year are as follows: Mary Louise Marshall (Tulane University), president; Dr. John F. Fulton (Yale University), vice-president; Frida Pliefke (Mayo Clinic), secretary; and Bertha B. Hallam (University of Oregon), treasurer.

RHEUMATOID ARTHRITIS ASSOCIATED WITH SPLENOMEGALY AND LEUKOPENIA*

ROBERT H. TALKOV, M.D.,† WALTER BAUER, M.D.,‡ AND CHARLES L. SHORT, M.D.

BOSTON

IN 1924, Felty¹ reported 5 cases of chronic arthritis in adults, with associated splenomegaly and leukopenia. The patients ranged from forty-five to sixty-five years of age and included 3 men and 2 women. All had experienced marked weight loss. Two had low-grade pyrexia. All showed a yellowish-brown pigmentation of the skin, usually confined to the exposed surfaces. Three patients exhibited enlarged lymph nodes, but none hepatomegaly. The arthritis was neither widespread nor severe. Roentgenograms in 3 cases revealed "infectious arthritis"; in another, no articular changes were noted. Leukopenia, with white-cell counts varying from 1000 to 4200, was a striking feature in each case. Four of the 5 patients had a mild secondary anemia. Felty suggested either that the triad represented a pathologic process caused by a noxa that concurrently affected the spleen, blood and joints or that the splenomegaly and leukopenia were entirely unrelated to the arthritis. Unfortunately, no pathological studies were obtained. Since this communication, a number of reports relating to patients with arthritis, splenomegaly and leukopenia have appeared; most of them have been referred to as cases of Felty's syndrome.

Having encountered this triad from time to time during the last thirteen years, we wish to place on record some of our observations. We shall first present the clinical data and autopsy findings of a case very similar to those described by Felty. We shall next attempt a critical analysis of this syndrome based on our clinical experi-

ence and a review of the pertinent literature, as well as to point out the various pitfalls that may be encountered if the term "Felty's syndrome" is used indiscriminately. Finally, we shall present our reasons for rejecting this term in favor of the more accurate designation, "rheumatoid arthritis."

CASE 1. Mrs. J. K. (MGH 13724), a 45-year-old woman, entered the hospital because of increasing weakness during the previous 3 months. For 2 years she had had arthritis involving primarily the knees, feet and spine. Constitutional symptoms were moderate except for marked weight loss. She had lost 1 year before entry, and approximately 6 months. Five years before entry, a goiter was discovered, and dietary treatment prescribed.

At the time of admission, she presented no evidence of infection. Physical findings were pallor, signs of anemia, enlargement of the spleen and of the kidneys (the edge being palpable 10 cm. below the right costal margin), a palpable enlargement of the cervical and axillary lymph nodes. The blood pressure was 130/80. The joints showed swelling and tenderness. The hands and fingers were stiff. Permanent flexion of the joints and inability to make the fingers readily evident. The knees were formerly being flexed; both knees were painful. The toes were painful.

The neck was hard. The spine was stiff. The spine was not de-

Examined. The differential count was 1600, with 10% eosinophils, 2% neutrophils. The erythrocytes were 4.9 per cent. The white cells were free hydro-

stools did not contain occult blood. The diagnosis of a primary blood disease could not be established. Roentgenologic examination showed marked narrowing of the knee joints, second and third metacarpophalangeal articulations and both wrists. Bony atrophy was prominent. The knees also showed subluxation and extensive marginal proliferation, with spur formation at the tendon attachments. The gastrointestinal and genitourinary tracts were normal radiologically. Attempts to demonstrate esophageal varices failed. Catheterized urine specimens at the time of admission showed the presence of a trace of albumin and 10 to 15 erythrocytes and occasional coarse granular casts per high-power field. Blood cultures were sterile.

The diabetes was readily controlled with dietary measures and supplementary insulin therapy. On the 3rd hospital day, the patient developed fever and pyuria. Urine cultures made 2 days later showed *Escherichia coli*. During the next few weeks, there appeared multiple decubiti, otitis media and endophthalmitis of the left eye, which finally required enucleation. The patient failed progressively, and died on the 38th hospital day.

Autopsy (14 hours post mortem).^{*} In addition to the anticipated urinary-tract, aural and skin infections, the following positive findings were observed.

Culture of the heart's blood showed *Esch. coli*. The liver weighed 1900 gm. and showed parenchymal-cell destruction, many gas bubbles and large clumps of bacilli. There was a comparatively slight neutrophilic reaction. The vertebral bone marrow showed a slight decrease in the number of fat cells, apparently because of a moderate hyperplasia of the red-cell elements, with large numbers of normoblasts and a fair number of megaloblasts. Although there were many mature polymorphonuclear cells, only occasional myelocytes were seen. The normal architecture of the lymph nodes was obscured by marked vascular engorgement and the complete absence of germinal centers. The sinuses were dilated and filled with erythrocytes, lymphocytes and monocytes; some of the last were large and contained phagocytized red cells. The pulp consisted of mature lymphocytes, was extremely vascular, and contained hemosiderin deposits. The spleen was enlarged, weighing 675 gm. On the surface, there was a white, firm, fibrotic area measuring 2.5 by 8.0 cm., interpreted as an old infarct. The normal architecture was indistinct, and the widely dilated sinusoids contained clumps of bacilli. The pulp was composed mostly of many polymorphonuclear cells, large mononuclear cells, erythrocytes and plasma cells. There were also occasional large phagocytes containing red blood cells.

Sections through the articulating surfaces of the patella and femur of one knee joint showed fibrous-tissue ankylosis, destruction of the articular cartilage and its replacement by dense fibrous tissue. Partial obliteration of the joint cavity had taken place, with the formation of smaller cavities lined by a thin layer of synovial cells. The synovial tissues exhibited slight lymphocytic infiltration and contained large pigment-filled phagocytes. The remaining cartilage was chiefly fibrous. The subchondral plate was interrupted in some places, and in many of these areas, the proliferating fibrous tissue had invaded the subchondral marrow spaces. Below the femoral articular surface, there was a large island of degenerating cartilage surrounded by bone trabeculae. A similar island of cartilage was found buried in the patella. All the bony structures showed moderate atrophy. The articular

changes described were those of late and relatively inactive rheumatoid arthritis.

The anatomic diagnoses were as follows: rheumatoid arthritis, generalized; septicemia (*Esch. coli*); otitis media, bilateral, acute; mastoiditis, bilateral; pleuritis, chronic fibrous; pulmonary tuberculosis, right apical, healed; pulmonary infarcts, right lower lobe, with healing; bronchopneumonia; hepatitis, acute, with necrosis; splenomegaly (nonspecific); splenic infarct, healed; pyelonephritis, bilateral, acute and chronic; cystitis, acute; and lymphadenitis, chronic nonspecific.

Although the post-mortem findings in this case indicated sepsis as the chief cause of many of the changes observed, it should be emphasized that the triad of rheumatoid arthritis, splenomegaly and leukopenia was present before clinical evidence of urinary sepsis was obtained.

Except for the terminal septicemia, this case was similar to those described by Felty. The clinical course was characteristic of rheumatoid arthritis, a diagnosis that was readily confirmed by histologic examination. Were the splenomegaly and persistent leukopenia expressions of the same disease or of a concurrent malady? It seems reasonable to assume that the leukopenia was a manifestation of rheumatoid arthritis. However, since splenomegaly is not uncommon in patients with chronic pyelonephritis,² the changes in the spleen may have been due, at least in part, to the pyelonephritis, which obviously antedated the clinical evidence of its presence.

The following are a few brief case histories that illustrate even more clearly that the simultaneous occurrence of rheumatoid arthritis and one of a number of diseases may produce a clinical picture like that described by Felty.

CASE 2. Miss C. W. (M.G.H. 20050), a 40-year-old woman, entered the hospital in February, 1940, because of gastric symptoms. A large gastric ulcer was demonstrated by x-ray examination. The patient readily became symptom free when placed on an ulcer regime. She stated that she had suffered from a severe progressive arthritis for 8 years. Further examination and studies revealed, in addition to the crippling rheumatoid arthritis, a slight generalized lymphadenopathy, a splenomegaly, a persistent leukopenia (white-cell counts varying from 3800 to 4000) and a mild hypochromic anemia, characteristic findings that some have termed Felty's syndrome. It was soon established that the splenomegaly and leukopenia were secondary to hepatic disease caused by cinchophen ingestion 6 years previously. In March, 1941, the patient died from generalized peritonitis following perforation of the gastric ulcer.

Autopsy. Examination confirmed the suspected cause of death and proved the presence of a healed acute yellow atrophy of the liver, chronic congestive splenomegaly with fibrosis, and rheumatoid arthritis.

CASE 3. Mrs. F. B. (M.G.H. 326626), a 67-year-old woman, was first seen in 1933. She had had moderately severe arthritis since 1931. When examined, she showed

^{*}We are indebted to Drs. Granville A. Bennett and Tracy B. Mallory for the report of the pathological findings.

the clinical picture and roentgenographic findings of fairly widespread rheumatoid arthritis. The spleen was readily palpable, and a leukopenia averaging about 3500 and a moderate hypochromic anemia were present. That these clinical findings were due to more than rheumatoid arthritis was suggested in 1934, when the patient expired suddenly because of a massive hematemesis.

Unfortunately, permission for a post mortem examination was not obtained. It was therefore impossible to exclude cirrhosis of the liver with esophageal varices as the cause not only of the fatal hemorrhage but also of the splenomegaly and leukopenia.

CASE 4 Mrs E S (MGH 32491), a 22 year-old woman, presented herself in December, 1940, because of apparent rheumatoid arthritis of 18 months' duration. Splenomegaly, moderate normochromic anemia, slight leukopenia and generalized lymphadenopathy were present. Further search revealed that the splenomegaly and anemia were of at least 11 years' duration, having been noted while the patient was under observation for rheumatic heart disease. Subsequent investigation established the diagnosis of familial hemolytic anemia, and splenectomy was successfully performed.

CASE 5 Mrs F K (MGH 338331), a 32 year old woman, presented the picture of rheumatoid arthritis, generalized adenopathy, splenomegaly, leukopenia and slight hypochromic anemia when first seen. However at subsequent examination, 4 years later, the spleen was no longer palpable and the leukopenia had vanished, and yet the arthritis had progressed somewhat in severity.

In view of these illuminating personal experiences, it seemed worth while to review the literature since 1924 to determine whether the reported cases corresponded to those described by Felty or represented rheumatoid arthritis in association with another disease.

It hardly seems just to attribute the origin of the confusing eponym, "Felty's syndrome," to the observer who first drew attention to this triad. Felty¹ clearly indicated that splenomegaly and leukopenia were known to occur in patients with arthritis but believed it unusual for all three to occur together. Although he stated that "one is more or less forced to the conclusion that the syndrome is a distinct clinical entity, of which the outstanding symptoms are those related to the joints, and the outstanding signs are the enlarged spleen and the blood picture," he did not imply that the articular disturbance was a segregated or unusual joint disease, and he carefully considered the necessity for the elimination of other concurrent pathologic lesions.

The origin of the term, 'Felty's syndrome,' must be directly attributed to Hanrahan and Miller,³ who so classified their case in 1932. Their patient, in addition to the triad of rheumatoid arthritis, splenomegaly and leukopenia, complained of belching and upper abdominal pain. The findings of hepatomegaly, urobilinuria, melena and anemia of the macrocytic type strongly

suggest the existence of an accompanying disease, such as cirrhosis of the liver, although histologic examination of the spleen after its removal revealed nothing specific.

Another illustration of possible hepatic disease occurring in a patient with articular manifestations and giving a clinical picture resembling Felty's cases was reported by Craven⁴ in 1934. This patient also had hepatomegaly and evidence of liver damage as measured by the bromsulfalein test of liver function. Sections of the spleen removed from this case were essentially the same as those reported by Hanrahan and Miller.³

Chronic gouty arthritis can on occasions clinically simulate rheumatoid arthritis.⁵ In the case reported by Fitz,⁶ a history of sudden recurring attacks of "rheumatism" eventually involving most of the joints, an elevated blood uric acid level and roentgenographic changes in certain of the smaller joints suggest that this patient may have had gouty arthritis. It is interesting to note von Jaksch's⁷ case report in 1908 of "arthritis urica" associated with splenomegaly and leukopenia, in which necropsy grossly confirmed the diagnosis of gouty arthritis. Unfortunately, no microscopic findings were reported.

In 1936, Reich⁸ reported a case of Felty's syndrome in which the white cell counts were 7200 and 5300 and in which the joints are not mentioned. In this twenty one year old man with a history of "rheumatism" at the age of six and with an aortic diastolic murmur, fever, night sweats and eventual death, the possibility of subacute bacterial endocarditis or active rheumatic fever was not excluded.

It is interesting that some observers not only have accepted this syndrome as an entity but also have essayed a search for its specific etiology. Singer and Levy⁹ considered this group a special form of sepsis lenta, believing *Streptococcus viridans* to be the causative agent. Unfortunately, their cases presented too many complicating factors to be clearly defined. *Str viridans* was isolated from the blood of their first case, and the course of the patient's illness was consistent with subacute bacterial endocarditis with fever, generalized petechiae, anemia and, finally, cardiac failure. At autopsy, however, the heart valves were normal, and no source of the bacteremia was found. Their second patient ran a more acute course, with a severe pancytopenia, and the bacteriologic and post mortem findings were similar to those described in the first case.

From the case report by Williams¹⁰ in 1936, one cannot be sure of the exact type of joint disease, the picture being consistent with either a specific infectious or a rheumatoid arthritis. Unfortunately,

the autopsy was restricted to the chest and abdomen, so that the post-mortem diagnosis of hypertrophic arthritis was based on examination of the spine. Williams believed the mechanism responsible for the syndrome to be a primary blood dyscrasia, with secondary articular involvement. From the clinical description given, one may consider it a case of malignant neutropenia, with an associated arthritis of unknown type. This was borne out by bone-marrow studies revealing hyperplasia and maturation arrest of the neutrophilic series.

Curtis and Pollard¹¹ concluded that so-called "Felty's syndrome" was merely a chance variant of ordinary rheumatoid arthritis, since calf-muscle biopsies from 4 patients with rheumatoid arthritis showed a similar picture to those taken from 4 patients with rheumatoid arthritis associated with splenomegaly and leukopenia and from 4 with splenomegaly and leukocytosis. We believe that the relation of muscle histology to joint disease is not sufficiently established to permit conclusions to be drawn. It should also be pointed out that 2 cases in the group reported by these authors had too many complicating features to be acceptable as unequivocally similar to Felty's cases, and that the spleen in another showed amyloid deposits in the follicles.

Diffuse chronic septic splenitis and healed and caseating tubercles in the lung were found at autopsy in the case described by Price and Schoenfeld¹² in 1934. This raises the question of differentiating pulmonary tuberculosis from rheumatoid arthritis as the cause for the splenomegaly in this patient, who appeared clinically to fall into the category under discussion.

Collins's¹³ conclusion that the clinical picture of the arthritis in his 2 cases did not differ from that of rheumatoid arthritis seems warranted. Pathological verification was not obtained.

Lack of adequate studies, before and after death, has been one of the primary difficulties encountered in the classification of cases reported as Felty's syndrome. However, the most exhaustive studies may fail to reveal the exact diagnosis. This was strikingly shown by Steinbrocker and Sesit¹⁴ in their description of a patient who corresponded clinically to Felty's cases. Varied and complete studies, including two lymph-node biopsies, were nonrevealing, and yet histologic study of the spleen after death showed Hodgkin's disease associated with terminal miliary tubercles. The joints were not examined.

It is readily evident that 11 of 14 cases reported in the literature as examples of Felty's syndrome strongly suggest the possibility that the unassociated accompanying disease was responsible for the

splenomegaly and leukopenia. As has been previously pointed out, the pitfalls encountered when this term is used indiscriminately are many. They are due, in great measure, to failure to exclude the existence of some concurrent disease responsible for the enlarged spleen and the leukopenia, as well as failure to realize that splenomegaly and leukopenia may be manifestations of rheumatoid arthritis.

The occurrence of splenomegaly and adenopathy in rheumatoid arthritis was first mentioned in 1896 by Chauffard and Ramond¹⁵ in adults, and in 1897 by Still¹⁶ in children. Since then, diverse figures for the incidence of splenomegaly have appeared: 6 per cent by Waterhouse,¹⁷ 8 per cent by Freund,¹⁸ 10 to 15 per cent by Dawson,¹⁹ 21 per cent by Coates and Delicati²⁰ and 23 per cent by McCrae.²¹ The frequency of lymphadenopathy in this disease has been variously reported as follows: Freund,¹⁸ 19 per cent; Coates and Delicati,²⁰ 53 per cent; Waterhouse,¹⁷ 96 per cent; and others who give no definite figures. These reported differences are probably due to varying assiduity in the search for lymph nodes and differences in criteria for denoting enlargement.

Although slight or moderate grades of leukopenia are not unusual in rheumatoid arthritis, severe neutropenia is rare.²² According to Collins,¹³ whose criteria for the upper limits of a definitely pathologic leukopenia are a white-cell count of 2000 or a neutrophil count of 1000, leukopenia occurs in less than 0.5 per cent of the cases. Incidentally, less than half the cases designated as Felty's syndrome fall within this strict definition. In our unselected series of 293 cases of rheumatoid arthritis, we have observed splenomegaly in 7 per cent, lymphadenopathy in 31 per cent and leukopenia consistently under 5000 in 1 per cent.

In view of these findings, there seems to be no need to assume that any combination of splenomegaly, adenopathy or leukopenia with rheumatoid arthritis represents a new pathologic entity. However, from the figures given, the triad of arthritis, splenomegaly and leukopenia is encountered very rarely. For this reason, numerous concurrent pathologic entities that may cause splenomegaly or leukopenia, or both, in patients with rheumatoid arthritis must be borne in mind. From our experience, the commoner maladies to be searched for are chronic liver disease (cirrhosis or healed acute yellow atrophy), pernicious anemia, leukemia, granulocytopenia, hemolytic anemia, amyloid disease, malignant lymphoma and various acute and chronic infections. In addition, lupus erythematosus disseminatus, dermatomyositis and periarteritis nodosa may present some or all of the features of arthritis, splenomegaly and

leukopenia, and must be considered in the differential diagnosis. We are fully aware of the bizarre and often unrecognizable picture presented by some of these conditions. It is a common experience that the condition may defy diagnosis until the truth is revealed at autopsy.

The evolution of the definition of the clinical entity, rheumatoid arthritis, has been beset with too many confusing permutations and the introduction of new terms to encourage their continuance. In Case 1, the articular disorder was obviously rheumatoid arthritis; the leukopenia was presumably a manifestation of the same disease. However, the splenomegaly, as noted above, may be attributed, at least in part, to the chronic pyelonephritis. Our experience and that of others show how often another disorder may be responsible for the splenomegaly and leukopenia observed in patients with rheumatoid arthritis. We therefore believe that the term "Felty's syndrome," which implies a separate pathologic entity, has no reasonable foundation and should be discarded. It is far more important to realize that rheumatoid arthritis is a generalized disease that may affect with varying frequency the lymph nodes, spleen, bone marrow and many other tissues besides the articular structures.

SUMMARY

The clinical record and autopsy findings of a patient whose pathologic picture was similar to the cases described by Felty are presented, with evidence demonstrating the articular disorder to be rheumatoid arthritis. The leukopenia was presumably a manifestation of the same pathologic process, whereas the splenomegaly may have resulted from the arthritis, the chronic pyelonephritis, or both.

The incidence of leukopenia and splenomegaly in association with rheumatoid arthritis, as noted in our clinical experience and in the literature, is enumerated. It is obvious that this triad as an expression of rheumatoid arthritis is but rarely en-

countered. In fact, we have been unable to find any pathologically verified case in the literature or in our own clinical material in which an extraneous cause of the splenomegaly and the leukopenia can be definitely eliminated.

The inadvisability of using the term, "Felty's syndrome," is pointed out. In the rare case in which an extraneous cause of splenomegaly and leukopenia can be eliminated, one should employ the more accurate name, "rheumatoid arthritis," with associated splenomegaly and leukopenia.

URINARY TYPHOID CARRIERS*

Report of a Case

WESTON T. BUDDINGTON, M.D.,† AND B. BARRETT GILMAN, M.D.‡

BOSTON

THE pyogenic faculty of the typhoid bacillus and the surgical complications of typhoid fever have been the subjects of medical reports and debate for many years. In 1898, Keen¹ published a study based on the analysis of 900 recorded cases in which he discussed the suppurative lesions caused by typhoid bacilli in nearly every organ of the body, including units of the gastrointestinal and genitourinary tracts. These two systems play the leading roles in the carrier state that is considered directly responsible for nearly half the cases of typhoid fever.

Just how frequently one of these systems becomes permanently involved is difficult to say; the bacteriology is a moot point in many of the cases reported in the literature. The records in Massachusetts² from 1937 to 1941 inclusive reveal that there were 405 cases of typhoid fever during that period. The patients were all followed very carefully, and 16 were found to be carriers, 1 being a urinary carrier. This is a much smaller proportion than that found in many other series, possibly because in Massachusetts a person is not classified as a carrier until he is proved to harbor the organism five or more months after his initial infection, and he is not placed on the carrier list until a year has elapsed. This rule avoids the inclusion of patients who excrete the organisms longer than usual during their convalescence. Addition of a name to the permanent carrier list excludes the patient from any occupation that involves the handling of food.

The persistent focus of typhoid infection that is responsible for the carrier state is centered in the gall bladder in most cases. Garbat,³ in his excellent monograph, presents evidence that "liver carriers," that is, carriers with chronic infection in the hepatic ducts or liver tissue, as well as "true intestinal carriers," do occur. Undoubtedly, these types are extremely rare.

Dehler⁴ is credited with being the first to suggest surgical treatment of the carrier state; his article was published in 1907. Since then, many patients have been subjected to surgery for this reason, the great majority for drainage or re-

moval of an infected gall bladder. These operations should not be undertaken unless a duodenal drainage has been done and the culture of the bile found to be positive for *Eberthella typhosa*. The reason for this, of course, is to rule out liver and intestinal carriers. With this precaution, excellent results from the surgical approach may be expected. Over 30 cases in Massachusetts have thus been operated on during a period of several years, with complete success in all but 1. This failure may have been due to a blind pocket of infection in the cystic duct that was not completely removed at the level of its junction with the common duct, or to retained calculi in one of these structures.

Although urinary carriers are far less commonly encountered than fecal carriers, their potential danger to the community is individually greater. This is due to the infectiousness of the excreta (as high as 43,000,000 organisms per cubic centimeter have been recorded³), to the frequency of urination, and to the carelessness in the disposal of urine that seems quite innocuous. Considering that bacilluria in this disease is often found, it is surprising that permanent urinary carriers are not commoner. Garbat³ estimates that 49 per cent of patients present organisms in their urine during convalescence, and believes that such organisms originate in the upper urinary tract in most cases. Of these cases of bacilluria, about 2.5 per cent remain positive for two or three months after the fever has subsided, presumably owing to the presence of renal areas of focal necrosis that discharge bacilli into the excretory passages of the kidney. A small number of this last group become the chronic urinary typhoid carriers, and may thus remain a menace to the health of the community for many years.

In most of the recorded cases of urinary-tract involvement, the carrier state has not received particular mention or emphasis, operation having been undertaken on ordinary surgical grounds for the drainage or removal of infected tissues. Whether the renal damage in such cases is a result of the typhoid infection, or whether the infection has seized on an organ already weakened by previous or concurrent disease, is a question still to be answered. Probably, both conditions occur, but present-day evidence favors the theory

*Presented at a meeting of the New England Section of the American Urological Association, Boston, April 24, 1941.

From the Urological Service, Carney Hospital, and the Division of Communicable Diseases, Massachusetts Department of Public Health.

†Assistant urologist, Carney Hospital.

‡Formerly, epidemiologist, Division of Communicable Diseases, Massachusetts Department of Public Health (Dr. Gilman died on May 31, 1941).

that the typhoid bacillus is generally the secondary invader. The value to the public health of the discovery of these urinary carriers is obvious, but one often fails to recognize the great importance to the individual of determining the reason for his condition. Where is chronic infection of the gall bladder with the typhoid bacillus weakens or destroys no vital organ, a persistent typhoid bacilluria implies upper urinary tract infection, and many of these cases have serious renal lesions.⁵⁻⁸ Thorough urologic study and appropriate treatment may well serve to correct both the disease and the carrier state, as in the following case.

CASE REPORT

The patient (C H 41515), a 37 year old truck driver became ill in August, 1939, and was admitted to his local hospital the following month with the provisional diagnosis of typhoid fever. It was found that he had been living in a household with a previously discovered carrier, and it was assumed that he had acquired his infection from this source through the medium of food or water. Little could be learned of his clinical course except that he suffered from headache, abdominal cramps and persistent fever ranging between 100 and 103°F. Laboratory study revealed a positive Widal test and two negative stool cultures. Examination of the urine carried out the day after admission, showed innumerable pus cells in the sediment; no other investigation was made. The nurses' notes state that at no time did the patient seem very ill, and after an apparently uneventful recovery he was discharged on October 28, 1939, about 6 weeks after admission.

Because cultures of mixed stool and urine specimens were still positive for typhoid bacteria a year later the patient's name was added to the carrier list of the Massachusetts Department of Public Health, and further study was begun. Specimens of bile obtained through a duodenal tube at this time (November 1, 1940) were negative, but a urine culture was positive, and the Department of Public Health, with the consent of the patient, arranged for complete urologic examination.

Little could be learned from the record, for there was no history of any serious illness or injury or of any complaint referable to the urinary tract, except for an occasional indefinite pain in the back. There had been no dysuria, hematuria, increased frequency or nocturia. Physical examination showed the patient to be a thin but otherwise healthy man with no significant defects. Neither kidney was palpable and there was no costo-vertebral tenderness. The external genitals were normal. Rectal examination revealed a small, firm, benign prostate, uniform in consistence. There was no thickening in either seminal vesicle region.

Cystoscopy revealed an irritable bladder, which tolerated no more than 120 cc of fluid. However, the mucosa, ureteral orifices, trigone and internal sphincter margin were normal in appearance. A No 5 Fr catheter was passed easily along the right ureter for 30 cm, and a clear, rhythmic drip was obtained, which later became blood tinged. On the left side, neither a No 5 nor a No 4 Fr catheter could be advanced beyond 22 cm. Phenolphthalein given intravenously appeared in 2 minutes on the right side, and a 10 minute collection showed an excretion of 9 per cent of the dye in 20 cc of urine. No determination of function could be made on the left,

since only a few drops of urine were obtained. The bladder urine contained many pus cells, free and in clumps and on culture *E. typhosa* was recovered. Urine from the right kidney was normal and showed no growth, whereas that from the left kidney was positive on culture for typhoid bacilli. A retrograde pyelogram revealed normal excretory passages on the right, but none of the opaque solution passed up the ureter on the left side beyond the point of obstruction, where an elliptical calculus was lodged (Fig 1). In the left renal area, there was a

FIGURE 1 Retrograde Pyelogram

The right side is normal but there is a large calculus at the tip of the ureteral catheter on the left

group of three small stones in the region of the lower pole of the kidney. Intravenous pyelograms again demonstrated good function on the right side, but there was very faint and delayed excretion of the dye on the left.

Two problems were thus presented: a badly damaged left kidney, as a result of ureteral obstruction and infection and a typhoid carrier state probably associated with this condition. After careful consideration of the medical and social aspects of the case, operation was decided on.

The patient re-entered the hospital on February 4, 1941. The interval history gave no new information. Physical examination showed no additional changes as compared with the earlier investigation, and an x-ray film showed the ureteral calculus to be in essentially the same position. Because of the rather long interval since the cystoscopic study the bladder inspection was repeated, with exploration of the left ureter and intravenous injection of indigo carmine. The bladder was normal, and the dye appeared at the right ureteral orifice in good concentration in 4½ minutes. No dye appeared on the left side during the period of the observation, which was extended to 50 minutes. A No 4 Fr ureteral catheter was blocked at

essentially the same level as before, and there was no drip of urine. Another attempt at a left retrograde pyelogram was unsuccessful; there was still complete obstruction of the ureter by the stone. Culture of the bladder urine again showed *E. typhosa*. The white-cell and red-cell counts were 5900 and 4,300,000 respectively; the hemoglobin was 95 per cent; and the differential count showed 70 per cent polymorphonuclears, 28 per cent lymphocytes, and 2 per cent basophils. The blood Wassermann reaction was negative, as was a blood culture and a Widal test. Blood sugar, calcium, phosphorus and uric acid determinations were all normal.

Operation was performed on February 6. A left lumbar incision was made, with preservation of the 11th and 12th intercostal nerves. When the renal fossa was entered, a large, soft kidney was found, with surprisingly few inflammatory adhesions. The renal parenchyma was extremely thin as a result of the severe hydronephrosis. The calculi noted in the x-ray films could be palpated in the lower calyx and upper ureter. Because of the extreme destructive changes present in the kidney and because of the serious infection known to exist, it was decided that nephrectomy should be performed. This was easily accomplished after a small vascular pedicle was isolated. A few centimeters of the upper ureter, including the region of the impacted calculus, was removed with the specimen.

The pathological report was as follows:

The specimen consists of a previously partially sectioned kidney weighing 120 gm. It measures 13 by 6 by 3 cm. There is an attached portion of the ureter, 8 cm. in length. When the incision is continued in the usual manner and the kidney divided into halves, the pelvis and calyces are greatly dilated, so that there remains only a narrow rim of renal parenchyma, measuring 3 mm. around the periphery. The pelvis and calyces are lined by glistening, gray, finely granular mucosa. Three stones are seen, the largest 0.4 cm. and having prongs on the surface. The ureter communicates with the pelvis and is markedly dilated, for the most part up to 2 cm. in circumference, but narrows suddenly to almost pinpoint size at the level where it is tied (Fig. 2).

Microscopic diagnosis: chronic pyelonephritis, hydronephrosis, hydroureter and nephrolithiasis. Cultures taken from the renal cavity and from the ureteral calculus showed *E. typhosa*.

The patient made an uneventful convalescence. A small amount of secondary wound infection at the posterior angle of the incision responded to drainage and the application of heat; culture of the pus failed to grow typhoid bacilli. The patient was discharged in good condition on March 2. He was seen 1 month and 2 months later in the Out-Patient Department, at which time he reported that he was feeling well and had no urinary complaints. Examination of the urine showed it to be normal except for 0 to 3 pus cells per high-power field in the sediment. The incision was dry and well healed.

Cultures of the bladder urine taken on the following dates were negative for typhoid infection: February 19 and 22; March 1, 10, 17, 24 and 27; May 5, 24 and 26;

FIGURE 2. Gross Specimen Sectioned Longitudinally.

Note the thin rim of parenchyma at the periphery and the dilated pelvis and calyces.

and July 5. The patient's name was removed from the carrier list shortly after the last negative culture.

SUMMARY

The typhoid-carrier state in most cases is due to residual chronic infection in the gall bladder. In a small but important percentage of cases, the focus of infection is in the urinary tract.

All persons in this latter group should have complete urologic investigation, for many of them have serious renal lesions.

An illustrative case is reported: surgical treatment corrected the carrier state and removed a dangerously infected kidney.

FURTHER EXPERIENCE WITH ELECTRIC-SHOCK THERAPY IN MENTAL DISEASE*

ABRAHAM MYLERTON, M.D.†

BOSTON

THE use of electric-shock therapy in the psychoses has become routine in many of the hospitals for mental diseases in the United States and in the private practice of many psychiatrists. An accumulated literature makes it possible to give with a greater degree of certainty the indications for the use of this method. These may be considered under two headings: injuries and risks, and accumulated experience regarding the type of case in which a favorable result may be anticipated and that in which little of value is to be expected.

Method of Treatment

Of the 123 patients in this series, 74 were treated by what I¹ have previously described as the "out-patient method"—that is, the patients reported at a place fitted out in hospital fashion with nurses and a physician in attendance, were given the shock treatment and, usually within one or two hours, went home. In a few cases, the patient was too disturbed after the treatment for the return home to be practical, and was transferred to a hospital for mental diseases to complete the series of treatments. In 2 other cases, injury precluded the return home, and transfer was made to in-patient care. In general, it can be stated that out-patient care of many psychiatric cases is very useful. It often makes commitment unnecessary, and although it must not in any sense be informal or without proper safeguard, it is, on the whole, as safe as inpatient care.

Injuries and Risks of Method

No fatalities have been recorded since the early days of the treatment. There is considerable difference of opinion concerning the pathologic cerebral changes produced. The Italian workers, Cerletti and Bini,² and Kalinowsky et al.^{3,4} found no serious neuropathologic changes in dogs. Smith and his co-workers^{5,6} found punctate hemorrhages in cats.

The fact that memory is definitely impaired for a variable period indicates that some organic change is produced. In the vast majority of cases, this impairment of memory disappears to a point where it is no longer discernible to the patient or

to those around him. In other cases, there is some subjective difficulty in memory for several months, although not to the point of incapacity or disability. Since the best clinical results are often obtained when the patient is shocked into amnesia, it may very well be that one of the conditions of recovery from a psychosis by the shock treatments depends on the temporary brain damage, probably most frequently swelling and possibly punctate hemorrhages. Only by speculation can one postulate a relevant change in any specific brain area or function.

Since the treatment has been in use in the United States for over three years and since cases have been observed for that period, it can now safely be stated that no severe damage of consequential type is done to the brain. Certainly, subdural and subarachnoid hemorrhages are not recorded in human beings. No neurologic signs have been noted after twenty-four hours in any of the cases that I have studied, and there is no record of such changes in the experience of other workers.

When the nature of the conditions treated and the suffering and doubtful prognosis are taken into account, it can on the whole be stated that the risk of brain damage by electric shock is fundamentally inconsequential when compared with the conditions treated: involutional melancholia, marked and severe depression, schizophrenia and the paranoid psychoses. Certainly, in an era in which hypothermia, hyperthermia, lobotomy and lobectomy are being carried out for the treatment of mental diseases, electric shock is, relatively speaking, a mild approach.

Injuries have been greatly reduced. The commonest complication is fracture of a vertebral transverse process. In this series of 123 cases, only 1 such fracture occurred. It was not disabling, and the patient recovered spontaneously and without orthopedic care. A fairly common type of injury in elderly people is either the precipitation of subdeltoid bursitis or its aggravation, if already present. Three such cases occurred in this series, and all responded to physiotherapy. The most unusual case of injury in the group was that of a fifty-year-old woman mentally sick for years with a chronic depressive state, presenting a moderate amount of osteoporosis common at her age and

an anemia of considerable degree, who had a fracture of both acetabulums, with displacement of the heads of the femurs into the pelvis. Since this patient is still under treatment, the physical outcome cannot be stated. Mentally, she became clear after one electric shock and has remained so. It may be of value, consequently, to study the amount of calcium in the blood and to make a careful study of the bony structure of the pelvis in certain cases, although in the case mentioned above there was no basis for such a study from the history of the patient.

Electrocardiographic changes have been described as occurring within the first twenty-four hours after shock treatment. The recording returns to normal, however, within the same twenty-four hours. This may mean that the contraindications for treatment are severe arteriosclerosis, cardiac disease and very marked circulatory involvement. My own experience does not indicate any great degree of danger even with existing cardiac disease, although decompensation and severe arterial disturbances are certainly sufficient reasons not to undertake the treatment.
